Prozac®

fluoxetine hydrochloride

Brief Summary. Consult the package insert for complete prescribing information.

Indication: For the treatment of depression.

Contraindications: Known hypersensitivity to Prozac.

Monamine Oxidase Inhibitors — There have been reports of serious, sometimes fatal, reactions in patients receiving fluoxetine in combination with an MAOI and in patients who have recently discontinued fluoxetine and are then started on an MAOI. Some cases presented with features resembling neuroleptic malignant syndrome.

Wait at least 14 days between discontinuing an MAOI and starting therapy with Prozac. Because of the long half-lives of fluoxetine and its active metabolite, wait at least 5 weeks between discontinuing Prozac and starting therapy with an MAOI. Prozac should not be used concomitantly with MAOIs.

Warnings: Rash and Possibly Allergic Events — Approximately 4% of 5,600 fluoxetine patients developed a rash and/or urticaria in premarketing testing. Almost a third of these discontinued therapy because of rash and/or associated systemic signs or symptoms. Reported in association with rash were fever, leukocytosis, arthralgias, edema, carpal tunnel syndrome, respiratory distress, lymphadenopathy, proteinuria, and mild transaminase elevation. Most patients improved promptly upon discontinuation of fluoxetine and/or adjunctive treatment with antihistamines or steroids, and all were reported to recover completely.

Of 2 patients who developed a serious cutaneous systemic illness during premarketing clinical trials, 1 was considered to have a leukocytoclastic vasculitis, and the other, a severe desquamating syndrome considered variously to be a vasculitis or erythema multiforme. Other patients have had systemic syndromes suggestive of serum sickness.

Since the introduction of Prozac, systemic events possibly related to vasculitis have developed in patients with rash. Although these events are rare, they may be serious, involving the lung, kidney, or liver. Death has been reported to occur in association with these systemic events.

Anaphylactoid events, including bronchospasm, angioedema, and urticaria alone and in combination, have been reported.

Pulmonary events, including inflammatory processes of varying histopathology and/or fibrosis, have been reported rarely. These events have occurred with dyspnea as the only preceding symptom.

Whether these systemic events and rash have a common underlying cause or represent immunologic responses is not known. Upon the appearance of rash or of other possibly allergic phenomena for which an alternative etiology cannot be identified, Prozac should be discontinued.

Precautions: General — **Anxiety, Nervousness, and Insomnia** — Reported by 10% to 15% of patients, 5% of whom discontinued fluoxetine.

Altered Appetite and Weight — Significant weight loss, especially in underweight patients, may be an undesirable result of treatment.

Approximately 9% of fluoxetine patients experienced anorexia in controlled clinical trials, an incidence approximately sixfold that seen with placebo. A weight loss >5% of body weight occurred in 13% of fluoxetine patients compared with 4% in those on placebo and 3% in those on tricyclics. However, only rarely did fluoxetine patients discontinue treatment because of weight loss.

Activation of Mania/Hypomania — Hypomania or mania occurred in approximately 1% of fluoxetine patients in premarketing testing.

Seizures — Twelve of 6,000 patients (0.2%) experienced convulsions (or, possibly, seizures). Prozac should be introduced with care in patients with a history of seizures.

Suicide — Close supervision of high-risk patients should accompany initial therapy. Prescriptions of Prozac should be written for the smallest quantity of capsules consistent with good patient management to reduce the risk of overdose.

The Long Elimination Half-Lives of Fluoxetine and Its Metabolites — Because of the long elimination half-lives of the parent drug (2 to 3 days) and its major active metabolite (7 to 9 days), changes in dose will not be fully reflected in plasma for several weeks, affecting both strategies for titration to final dose and withdrawal from treatment.

Use in Patients with Concomitant Illness — Caution is advisable in patients with diseases or conditions that could affect metabolism or hemodynamic responses.

Fluoxetine has not been evaluated or used to any appreciable extent in patients with a recent history of myocardial infarction or unstable heart disease. ECGs of 312 patients who received Prozac in double-blind trials were retrospectively evaluated; no conduction abnormalities that resulted in heart block were observed. The mean heart rate was reduced by approximately 3 beats/min.

In subjects with cirrhosis, the clearances of fluoxetine and its active metabolite were decreased. A lower or less frequent dose should be used in patients with cirrhosis.

Fluoxetine should be used with caution in patients with severe renal impairment.

In patients with diabetes, Prozac may alter glycemic control. Hypoglycemia has occurred during therapy with Prozac, and hyperglycemia has developed following discontinuation. Insulin and/or oral hypoglycemic dosage may need to be adjusted when fluoxetine therapy is instituted or discontinued.

Interference with Cognitive and Motor Performance — Any psychoactive drug may impair judgment, thinking, or motor skills, and patients should be cautioned about operating hazardous machinery, including automobiles, until they are reasonably certain that the drug does not affect them adversely.

Information for Patients — Physicians should advise their patients to notify them if they:

- are taking or plan to take any prescription or over-the-counter drugs or alcohol
- become pregnant or intend to become pregnant during therapy
- are breast feeding an infant
- develop a rash or hives

Drug Interactions — **Tryptophan** — Five patients receiving tryptophan experienced adverse reactions, including agitation, restlessness, and gastrointestinal distress.

Monamine Oxidase Inhibitors — See Contraindications.

Other Antidepressants — There have been greater than 2-fold increases of previously stable plasma levels of other antidepressants when Prozac has been administered in combination with these agents.

Lithium — There have been reports of both increased and decreased lithium levels and lithium toxicity. Lithium levels should be monitored.

Diazepam Clearance — The half-life of diazepam may be prolonged in some patients.

Drugs Tightly Bound to Plasma Proteins — Because fluoxetine is tightly bound to plasma protein, the concurrent administration of fluoxetine and another tightly bound drug may cause a shift in plasma concentrations potentially resulting in an adverse effect. Adverse effects may also result from displacement of protein-bound fluoxetine by other tightly bound drugs.

CNS-Active Drugs — Caution is advised if the concomitant administration of Prozac and such drugs is required.

Electroconvulsive Therapy — There have been rare reports of prolonged seizures in patients on fluoxetine receiving ECT treatment.

Carcinogenesis, Mutagenesis, Impairment of Fertility — There is no evidence of carcinogenicity, mutagenicity, or impairment of fertility with Prozac.

The dietary administration of fluoxetine to rats and mice for 2 years at doses approximately 7.5 and 9.0 times the maximum human dose (80 mg) respectively revealed no evidence of carcinogenicity.

Fluoxetine and norfluoxetine have been shown to have no genotoxic effects based on the following assays: bacterial mutation assay, DNA repair assay in cultured rat hepatocytes, mouse lymphoma assay, and in vivo sister chromatid exchange assay in Chinese hamster bone marrow cells.

Two fertility studies in rats at doses approximately 5 and 9 times the maximum human dose (80 mg) respectively revealed no adverse effects on fertility. A slight decrease in neonatal survival was noted, probably associated with depressed maternal food consumption and suppressed weight gain.

Pregnancy — **Teratogenic Effects** — **Pregnancy Category B** — Reproduction studies in rats and rabbits at doses 9 and 11 times the maximum human dose (80 mg) respectively revealed no evidence of harm to the fetus. Although there have been no adequate and well-controlled studies in pregnant women, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery — The effect of Prozac on labor and delivery in humans is unknown.

Nursing Mothers — Because Prozac is known to be excreted in human milk, caution should be exercised when Prozac is administered to a nursing woman.

Use in Children — Safety and effectiveness in children have not been established.

Use in the Elderly — In clinical studies of several hundred elderly patients, no unusual adverse age-related phenomena were identified. However, these data are insufficient to rule out possible age-related differences during chronic use, particularly in elderly patients with concomitant systemic illnesses or those receiving concomitant drugs.

Hypotension — Hypotension (some cases with serum Na <110 mmol/L) has been reported, which appeared to be reversible on drug discontinuation. Some cases were possibly due to SIAHD, and the majority have been in older patients and those taking diuretics or otherwise volume depleted.

Platelet Function — There have been rare reports of altered platelet function and/or abnormal results from laboratory studies in patients taking fluoxetine. While there have been reports of abnormal bleeding in several patients taking fluoxetine, it is unclear whether fluoxetine had a causative role.

Adverse Reactions: Commonly Observed — Nervous system complaints, including anxiety, nervousness, and insomnia; drowsiness and fatigue or asthenia; tremor; sweating; gastrointestinal complaints, including anorexia, nausea, and diarrhea; and dizziness or lightheadedness.

Associated With Discontinuation of Treatment — Fifteen percent of 4,000 clinical trial patients discontinued fluoxetine due to an adverse event. The more common events included: psychiatric (5.3%), primarily nervousness, anxiety, and insomnia; digestive (3.0%), primarily nausea; nervous system (1.6%), primarily dizziness; body as a whole (1.5%), primarily asthenia and headache; and skin (1.4%), primarily rash and pruritus.

Incidence in Controlled Clinical Trials — The accompanying table enumerates adverse events that occurred at a frequency of $\geq 1\%$ in controlled trials.

Other Events Observed During Premarketing Evaluation in 5,600 Fluoxetine Patients — Frequent adverse events are defined as those occurring on 1 or more occasions in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1,000 patients; rare events are those occurring in less than 1/1,000 patients.

Body as a Whole — **Frequent:** chills; **Infrequent:** chills and fever, cyst, face edema, hangover effect, jaw pain, malaise, neck pain, neck rigidity, and pelvic pain; **Rare:** abdomen enlarged, callusitis, hydrocephalus, hypothermia, LE syndrome, moniliasis, and serum sickness.

Cardiovascular System — **Infrequent:** angina pectoris, arrhythmia, hemorrhage, hypertension, hypotension, migraine, postural hypotension, syncope, and tachycardia; **Rare:** AV block first-degree, bradycardia, bundle branch block, cerebral ischemia, myocardial infarct, thrombophlebitis, vascular headache, and ventricular arrhythmia.

Digestive System — **Frequent:** increased appetite; **Infrequent:** aphthous stomatitis, dysphagia, eructation, esophagitis, gastritis, gingivitis, glossitis, liver function tests abnormal, melena, stomatitis, thirst; **Rare:** bloody diarrhea, cholecystitis, cholelithiasis, colitis, duodenal ulcer, enteritis, fecal incontinence, hematemesis, hepatitis, hepatomegaly, hyperchlorhydria, increased salivation, jaundice, liver tenderness, mouth ulceration, salivary gland enlargement, stomach ulcer, tongue discoloration, and tongue edema.

Endocrine System — **Infrequent:** hypothyroidism; **Rare:** goiter and hyperthyroidism.

Hemic and Lymphatic System — **Infrequent:** anemia and lymphadenopathy; **Rare:** bleeding time increased, blood dyscrasia, leukopenia, lymphocytosis, petechia, purpura, sedimentation rate increased, and thrombocytopenia.

Metabolic and Nutritional — **Frequent:** weight loss; **Infrequent:** generalized edema, hypoglycemia, peripheral edema, and weight gain; **Rare:** dehydration, gout, hypercholesterolemia, hyperglycemia, hyperlipemia, hypoglycemic reaction, hypokalemia, hyponatremia, and iron deficiency anemia.

Musculoskeletal System — **Infrequent:** arthritis, bone pain, bursitis, tenosynovitis, and twitching; **Rare:** bone necrosis, chondrodysplasia, muscle hemorrhage, myositis, osteoporosis, pathological fracture, and rheumatoid arthritis.

Nervous System — **Frequent:** abnormal dreams and agitation; **Infrequent:** abnormal gait, acute brain syndrome, akathisia, amnesia, apathy, ataxia, buccoglossal syndrome, CNS stimulation, convulsion,

TREATMENT-EMERGENT ADVERSE EXPERIENCE INCIDENCE IN PLACEBO-CONTROLLED CLINICAL TRIALS

Body System/ Adverse Event*	Percentage of Patients Reporting Event		Percentage of Patients Reporting Event

*Events reported by $\geq 1\%$ of fluoxetine patients are included.
— Incidence <1%.

delusions, depersonalization, emotional lability, euphoria, hallucinations, hostility, hyperkinesia, hyposthesia, incoordination, libido increased, manic reaction, neuralgia, neuropathia, paranoid reaction, psychosis, and vertigo; **Rare:** abnormal electroencephalogram, anti-social reaction, chronic brain syndrome, circumoral paresthesia, CNS depression, coma, dysarthria, dystonia, extrapyramidal syndrome, hypertonia, hysteria, myoclonus, nystagmus, paralysis, reflexes decreased, stupor, and torticollis.

Respiratory System — **Frequent:** bronchitis, rhinitis, and yawn; **Infrequent:** asthma, epistaxis, hiccup, hyperventilation, and pneumonia; **Rare:** apnea, hemoptysis, hypoxia, larynx edema, lung edema, lung fibrosis/atelectasis, and pleural effusion.

Skin and Appendages — **Infrequent:** acne, alopecia, contact dermatitis, dry skin, herpes simplex, maculopapular rash, and urticaria; **Rare:** eczema, erythema multiforme, fungal dermatitis, herpes zoster, hirsutism, psoriasis, purpuric rash, pustular rash, seborrhea, skin discoloration, skin hypertrophy, subcutaneous nodule, and vesiculobullous rash.

Special Senses — **Infrequent:** amblyopia, conjunctivitis, ear pain, eye pain, mydriasis, photophobia, and tinnitus; **Rare:** blepharitis, cataract, corneal lesion, deafness, diplopia, eye hemorrhage, glaucoma, iritis, ptosis, strabismus, and taste loss.

Urogenital System — **Infrequent:** abnormal ejaculation, amenorrhea, breast pain, cystitis, dysuria, fibrocystic breast, impotence, leukorrhea, menopause, menorrhagia, ovarian disorder, urinary incontinence, urinary retention, urinary urgency, urination impaired, and vaginitis; **Rare:** abortion, albuminuria, breast enlargement, dyspareunia, epididymitis, female lactation, hematuria, hypomenorrhea, kidney calculus, metrorrhagia, orchitis, polyuria, pyelonephritis, pyuria, salpingitis, urethral pain, urethritis, urinary tract disorder, urolithiasis, uterine hemorrhage, uterine spasm, and vaginal hemorrhage.

Postintroduction Reports — Voluntary reports of adverse events temporally associated with Prozac that have been received since market introduction and which may have no causal relationship with the drug include the following: aplastic anemia, cerebral vascular accident, confusion, dyskinesia (including, for example, a case of buccal-lingual-masticatory syndrome with involuntary tongue protrusion reported to develop in a 77-year old female after 5 weeks of fluoxetine therapy and which completely resolved over the next few months following drug discontinuation), ecchymoses, eosinophilic pneumonia, gastrointestinal hemorrhage, hyperprolactinemia, immune-related hemolytic anemia, movement disorders developing in patients with risk factors including drugs associated with such events and worsening of preexisting movement disorders, neuroleptic malignant syndrome-like events, pancreatitis, pancytopenia, suicidal ideation, thrombocytopenia, thrombotic purpura, vaginal bleeding after drug withdrawal, and violent behaviors.

Overdose: Human Experience — As of December 1987, there were 2 deaths among approximately 38 reports of acute overdose with fluoxetine, either alone or in combination with other drugs and/or alcohol. One death involved a combined overdose with approximately 1,800 mg of fluoxetine and an undetermined amount of meprobamate. A second death involved fluoxetine, codeine, and temazepam.

One other patient who reportedly took 3,000 mg of fluoxetine experienced 2 grand mal seizures that remitted spontaneously without specific anticonvulsant treatment. The actual amount of drug absorbed may have been less due to vomiting.

Nausea and vomiting were prominent in overdoses involving high fluoxetine doses. Other prominent symptoms of overdose included agitation, restlessness, hypomania, and other signs of CNS excitation. Except for the 2 deaths noted above, all other overdose cases recovered without residua.

Since introduction, reports of death attributed to overdose of fluoxetine alone have been extremely rare.

FLEXIBILITY

**PRINTED SELF TEST
AND TREATMENT RESULTS**

**ADDITIONAL FEATURES INCLUDED
WITH ALL SR MODELS ARE:**

- EEG instrumentation amplifier
- Built-in 2 channel digital chart recorder
- Numeric timing marks during monitoring
- Printed record of energy level
- Printed date and time of treatment
- ECG instrumentation amplifier
- Selectable single or dual channel
- Printed record of treatment and self test
- Printed record of stimulus parameters
- Modular design for maximum flexibility

SR/JR FEATURES INCLUDE:

- Continuous reading of energy in Joules
- Tiltable Liquid Crystal Display
- Bi-polar brief pulse stimulus
- Adjustable constant current stimulus
- Audible warning prior to treatment
- Remote control capabilities
- 100% expected seizure induction
- Totally isolated for maximum safety
- Single or multiple energy control(s)
- All parameters displayed in text form
- Increased energy for difficult cases
- Built-in self test for patient safety
- Steady warning tone during treatment
- Protected STIMULUS CONTROL push button
- Timing accuracy better than .1%
- 1 year parts and labor warranty
- Operates on 120 or 240 VAC
- Complete with all accessories

**DIRECTOR
PHYSICIAN HEALTH SERVICES (PHS)**

The Massachusetts Medical Society has created a full-time position for its Director of Physician Health Services. He/She will be responsible for managing the day-to-day clinical and administrative requirements of the PHS program. Duties will include reviewing existing systems and, if necessary, developing new ones for the effective outreach, intervention and treatment of impaired physicians. In addition, the Director will be responsible for the program's compliance with established protocols and supervision of staff. The Director will also function as the Society's liaison to the Massachusetts Board of Registration in Medicine in matters concerning impaired physicians. Other duties will include financial management of the program as well as assisting with fund raising and development.

This position requires an M.D. degree, Board Certification in psychiatry with eligibility to sit for added qualifications in Addiction Psychiatry or Board Certification in Internal Medicine with certification by the American Society of Addiction Medicine (ASAM). At least 8-10 years of direct experience in the diagnosis and treatment of substance abuse is required. Demonstrated leadership is necessary. In the effective management (including staff supervision) of programs providing intervention, treatment, and rehabilitation for drug and alcohol problems for professionals. An ability to relate effectively to a multitude of diverse organizations such as hospital medical staff, consumer groups and government agencies is also necessary.

Interested candidates should submit a letter of interest and a current copy of their curriculum vitae to: Search Committee, Human Resources Department, Massachusetts Medical Society, 1440 Main Street, Waltham, MA 02154. An equal opportunity employer.

MASSACHUSETTS MEDICAL SOCIETY

ROCHE

Enhancing The Lives Of Millions
By Focusing On Research

**CLINICAL RESEARCH/CENTRAL NERVOUS SYSTEM
PSYCHIATRY/NEUROLOGY**

Skilled Physicians have the capacity to touch the lives of many. At Hoffmann-La Roche, we give our colleagues the resources and sophisticated technology to advance the pharmaceuticals that impact lives worldwide. This ongoing effort has created two opportunities for MDs to share in this commitment.

ASSOCIATE DIRECTOR, MD

Join our respected international team whose goal is the timely development of drugs for worldwide markets. Your demonstrated medical and research capabilities will be applied in implementing clinical studies of new compounds for the treatment of depression and schizophrenia.

The successful candidate will be a Board Certified Psychiatrist with a strong research orientation. In addition, 1-3 years of experience in the pharmaceutical industry is preferred. **RESPOND TO DEPT. LH172CP**

Enjoy the advantages of working alongside talented professionals in an environment conducive to intellectual and professional growth. We offer competitive salaries, annual bonus contingent upon years of service and a total family care benefits package that starts when you do. Interested candidates should send C.V./resume, salary history and requirements, indicating appropriate department code, to: Ms. Lynn Harac, Staffing Department, Hoffmann-La Roche Inc., Nutley, NJ 07110-1199. We are an equal opportunity employer.

ASSISTANT DIRECTOR, MD

Become part of a team that provides clinical input concerning the development of various compounds in the fields of dementia, depression and neuroleptics. An additional facet involves collaborating with program directors in planning, conducting and evaluating clinical pharmacological projects.

The successful candidate will be a critical thinker with the desire to learn and work in an industry setting. Training in psychiatry or neurology is preferred. **RESPOND TO DEPT. LH182CP**

NEW FROM THE FREE PRESS

FAMILY HEALING **Tales of Hope and Renewal** **from Family Therapy** **Salvador Minuchin and** **Michael P. Nichols**

The family, source of our greatest hope for happiness, sometimes turns out to be the source of our greatest disappointment. Now, in the culmination of his lifework, world-renowned family therapist Salvador Minuchin reveals how his own personal experiences shaped his understanding of the family and his ability to cut through the knots of family dynamics. His confrontational yet compassionate style of therapy unlocks self-defeating patterns that foster marital conflict, difficulties with children, problems adjusting to old age and retirement, and other crises at each stage of the family life cycle.

1992 0-02-921295-2 \$22.95

SHAME **The Exposed Self** **Michael Lewis**

"Lewis brilliantly illuminates the nature of shame and its impact in our daily life, uniquely combining scholarly research, stories from everyday life, and clinical cases from his own practice. Lucid and insightful, it is must reading for scholars and laymen, researchers in emotion and development, and clinical practitioners."

—Paul Ekman, author of *Telling Lies and Why Kids Lie*

1992 0-02-918881-4 \$24.95

BREAKING **DESTRUCTIVE** **PATTERNS**

Multiple Strategies for
Treating Partner Abuse

Janet A. Geller, Center for
the Study of Family Abuse

"Janet Geller's report from the front lines of battering is very illuminating. It has just the right mixture of vivid vignettes and cogent conceptualization. It can't help but be useful and interesting to the widest range of professional and non-professional readers."

—Richard Rabkin, M.D.,
New York University

1992 0-02-911605-8 \$27.95

VOYAGES OF **THE HEART**

Living an Emotionally
Creative Life

James R. Averill,
University of Massachusetts and
Elma P. Nunley

"Averill and Nunley have combined impressive historical scholarship with clinical experience to produce an interesting, provocative, and unusual treatment of the emotions. Those interested in emotion from a personal standpoint, or merely curious intellectually, should find it absorbing."

—Richard S. Lazarus, Ph.D.,
University of California, Berkeley

1992 0-02-901108-6 \$22.95

THE DANGEROUS **EDGE**

The Psychology
of Excitement

Michael Apter,
Northwestern University

"Freud supposed that what human beings most wanted was a state of tranquillity following the discharge of all tensions. Freud was wrong. Apter rightly stresses man's need for arousal and excitement; a need so pressing that it must find an outlet even if it leads to danger and destruction. An important, challenging book."

—Anthony Storr, author of *Solitude*

1992 0-02-900765-8 \$22.95

FROM PARALYSIS **TO FATIGUE**

A History of Psychosomatic
Illness in the Modern Era

Edward Shorter,
University of Toronto

"A fascinating adventure into the borderland between social and medical history. Shorter uses the graphic clinical records of real people to indicate the intricate connection between individual pain and cultural choice. In a decade in which our generation has confronted a variety of elusive ailments, Shorter's historical perspective will prove enlightening."

—Charles E. Rosenberg, author of
The Care of Strangers: The Rise
of America's Hospital System

1992 0-02-928665-4 \$24.95

SHATTERED **ASSUMPTIONS**

Towards a New
Psychology of Trauma

Ronnie Janoff-Bulman,
University of Massachusetts,
Amherst

"Combining an excellent review of existing research and wise insights about treatment, this book should be read by all people interested in seeking to understand the basic assumptions of traumatized people who need to regain a sense of mastery in an unpredictable world."

—Bessel van der Kolk, M.D.,
Director, The Trauma Clinic,
Massachusetts General Hospital,
Harvard Medical School

1992 0-02-916015-4 \$24.95

INSTINCTS, ARCHETYPES AND SYMBOLS:

James P. HENRY

Instincts, Archetypes and Symbols: An Approach to the Physiology of Religious Experience

James P. Henry, M.D., Ph.D.

A most revealing neurological account of religious psychology as previously understood by Jung and William James. The numinous is interpreted in terms of instinctual processes related to an inner need for harmonizing intellect and the emotions. This is the Grail for people in search for a modern perception of meaning in its ultimate depths.

West Coast Psychiatry Board Review: Preparation for Part II

FEBRUARY 12-14, 1993

THE CATAMARAN RESORT HOTEL, SAN DIEGO, CALIFORNIA

Small group sessions led by experienced UCSD faculty will focus on techniques of information gathering, conduct during the interviewing process and the organization and presentation of data to examiners. All participants will have the opportunity to be examined on either a live or videotaped patient interview. A hosted luncheon on the first day will feature guest speakers presenting some very valuable tips to help you manage your test-taking anxiety.

The major emphases of this intensive program will be on the practical aspects of the exam:

- ★ What to anticipate
- ★ How to prepare
- ★ How to conduct a time-limited patient interview
- ★ How to organize clinical observations
- ★ How to manage your test-taking anxiety.

To request a brochure with further information, please contact:
West Coast Psychiatry Board Review
7916 Convey Court, San Diego, CA 92111
Phone: (619) 565-9921

☐ Please send me _____ copies of the West Coast Psychiatry Board Review:
Preparation for Part II brochure.

ESKALITH CR®

brand of LITHIUM CARBONATE 450 mg
Controlled Release Tablets

See complete prescribing information in SmithKline Beecham Pharmaceuticals literature or PDR. The following is a brief summary.

WARNING

Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy [see DOSAGE AND ADMINISTRATION in the complete prescribing information].

INDICATIONS

Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in those manic-depressive patients with a history of mania.

WARNINGS

Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, or sodium depletion.

Chronic lithium therapy may be associated with diminution of renal concentrating ability. Such patients should be carefully managed to avoid dehydration with resulting lithium retention and toxicity. Morphologic changes with glomerular and interstitial fibrosis and nephron atrophy have been reported. Morphologic changes have also been seen in manic-depressive patients never exposed to lithium. During lithium therapy, progressive or sudden changes in renal function, even within the normal range, indicate the need for reevaluation of treatment.

An encephalopathic syndrome [characterized by weakness, lethargy, fever, tremulousness and confusion, extrapyramidal symptoms, leukocytosis, elevated serum enzymes, BUN and FBG] has occurred in a few patients treated with lithium plus a neuroleptic. In some instances, the syndrome was followed by irreversible brain damage. Patients receiving such combined therapy should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness.

Lithium may prolong the effects of neuromuscular blocking agents. Such agents should be given with caution to patients receiving lithium.

Lithium carbonate may cause fetal harm when administered to a pregnant woman. If a patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Nursing should not be undertaken during lithium therapy except in rare and unusual circumstances.

Not recommended in children under 12.

Elderly patients often require lower lithium dosages to achieve therapeutic serum levels. They may also exhibit adverse reactions at serum levels ordinarily tolerated by younger patients.

PRECAUTIONS

Caution should be used when lithium and diuretics are used concomitantly. Patients receiving such combined therapy should have serum lithium levels monitored closely and the lithium dosage adjusted if necessary.

Sweating, diarrhea and concomitant infection with elevated temperatures may also necessitate a temporary reduction or cessation of medication.

Indomethacin and piroxicam have been reported to increase significantly, steady state plasma lithium levels. There is also some evidence that other nonsteroidal anti-inflammatory agents may have a similar effect. When such combinations are used, increased plasma lithium level monitoring is recommended. Concurrent use of metronidazole with lithium may provoke lithium toxicity due to reduced renal clearance. Monitor patients receiving such combined therapy closely.

When used with angiotensin-converting enzyme inhibitors, such as enalapril and captopril, lithium dosage may need to be decreased; measure plasma lithium levels more often.

Concurrent use of calcium channel blocking agents with lithium may increase the risk of neurotoxicity in the form of ataxia, tremors, nausea, vomiting, diarrhea and/or tinnitus. Caution is recommended.

ADVERSE REACTIONS

Adverse reactions may be encountered at serum lithium levels below 1.5 mEq/L. Mild to moderate adverse reactions may occur at levels from 1.5 to 2.5 mEq/L, and moderate to severe reactions may be seen at levels of 2.0 mEq/L and above. Fine hand tremor, polyuria and mild thirst may occur during initial therapy and may persist throughout treatment. Transient and mild nausea and general discomfort may also appear during initial therapy. These side effects usually subside with continued treatment or a temporary reduction or cessation of dosage. Diarrhea, vomiting, drowsiness, muscular weakness and lack of coordination may be early signs of lithium intoxication, and can occur at lithium levels below 2.0 mEq/L. At higher levels, ataxia, giddiness, tinnitus, blurred vision and a large output of dilute urine may be seen. Serum lithium levels above 3.0 mEq/L may produce a complex clinical picture, involving multiple organs and organ systems. Serum lithium levels should not be permitted to exceed 2.0 mEq/L during the acute treatment phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range. **Neuromuscular/Central Nervous System**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), hyperreflexia, ataxia, choreo-athetoid movements, hyperactive deep tendon reflex, extrapyramidal symptoms including acute dystonia, cogwheel rigidity, blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, downbeat nystagmus, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma, tongue movements, tics, tinnitus, hallucinations, poor memory, slowed intellectual functioning, started response, worsening of organic brain syndromes. **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse, bradycardia, sinus node dysfunction with severe bradycardia [which may result in syncope]; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea, gastritis, salivary gland swelling, abdominal pain, excessive salivation, flatulence, indigestion; **Genitourinary**—glycosuria, decreased creatinine clearance, albuminuria, oliguria and symptoms of nephrogenic diabetes insipidus including polyuria, thirst and polydipsia; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, acne, chronic folliculitis, xerosis cutis, psoriasis or its exacerbation, generalized pruritus with or without rash, cutaneous ulcers, angioedema; **Autonomic**—blurred vision, dry mouth, impotence/sexual dysfunction; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism [including myxedema] accompanied by lower T_3 and T_4 uptake may be elevated. [See PRECAUTIONS.] Paradoxically, rare cases of hyperthyroidism have been reported; **EKG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, exophthalmos, dehydration, weight loss, leukocytosis, headache, transient hyperglycemia, hypercalcemia, hyperparathyroidism, excessive weight gain, edematous swelling of ankles or wrists, metallic taste, dysgeusia/taste distortion, salty taste, thirst, swollen lips, tightness in chest, swollen and/or painful joints, fever, polyarthralgia, dental caries. Some reports of nephrogenic diabetes insipidus, hyperparathyroidism and hypothyroidism which persist after lithium discontinuation have been received.

A few reports have been received of the development of painful discoloration of fingers and toes and coldness of the extremities within one day of the starting of treatment with lithium. The mechanism through which these symptoms [resembling Raynaud's syndrome] developed is not known. Recovery followed discontinuance.

Cases of pseudotumor cerebri [increased intracranial pressure and papilledema] have been reported with lithium use. Lithium should be discontinued, if clinically possible, if this syndrome occurs.

HOW SUPPLIED

Controlled Release Tablets containing 450 mg lithium carbonate per tablet, in bottles of 100.

Calendar

For free listing of your organization's official annual or regional meeting, please send us the following information: sponsor, location, inclusive dates, type and number of continuing education credits (if available), and the name, address, and telephone number of the person or group to contact for more information. All notices and changes must be received no later than 120 days before the first day of the month of desired publication and should be addressed to Calendar, American Journal of Psychiatry, 1400 K St., N.W., Washington, DC 20005. Because of space limitations, only listings of meetings of the greatest interest to Journal readers will be included.

SEPTEMBER

September 2-4, 6th International Marcé Society Conference, "Recent Advances in Child Bearing and Mental Health," Edinburgh Conference Centre, Heriot-Watt University. Contact: Conference Secretariat, 1 Willoughby Street, Beeston, Nottingham NG9 2LT, United Kingdom; 44-602-436323.

September 3-5, annual meeting, International Federation of Psychoanalytic Societies, Munich. Contact: Marja Lindqvist, F.M. Secretary-General, Lansitie 9, 02160 Espoo, Finland; 358-0-426425.

September 8-13, annual meeting, National Alliance for the Mentally Ill, Washington, D.C. Contact: Laurie M. Flynn, Executive Director, 2101 Wilson Blvd., Suite 302, Arlington, VA 22201; 703-524-7600.

September 11-12, national conference, "Psychosocial Oncology: Enhancing Patient and Family Care" (14 hours of CME category 1 credit), Beverly Hills, Calif. Contact: Deane L. Wolcott, M.D., the Cedars-Sinai Comprehensive Cancer Center, 8700 Beverly Blvd., Los Angeles, CA 90048; 310-855-5486.

September 11-14, annual meeting, Royal College of Physicians and Surgeons of Canada, Ottawa. Contact: Dr. G.D. Hurteau, Executive Director, 74 Stanley Avenue, Ottawa, Ont. K1M 1P4, Canada; 613-746-8177.

September 14-17, annual meeting, American College of Emergency Physicians, Seattle. Contact: Colin C. Rorrie, Jr., Ph.D., Executive Director, P.O. Box 619911, Dallas, TX 75261-9911; 214-550-0911.

September 15-18, 2nd International Symposium, "Serotonin: From Cell Biology to Pharmacology and Therapeutics," Baylor College of Medicine, Giovanni Lorenzini Medical Foundation, and the Serotonin Club, Houston. Contact: Giovanni Lorenzini Medical Foundation, Baylor College of Medicine, Room 826E, One Baylor Plaza, Houston, TX 77030; 713-797-0401 (tel), 713-796-8853 (fax).

September 16-18, annual meeting, Canadian Psychiatric Association, Montreal. Contact: Canadian Psychiatric Association, 294 Albert Street, Suite 204, Ottawa, Ont. K1P 6E6, Canada; 613-234-2815.

September 18-20, annual meeting, Epilepsy Foundation of America, Alexandria, Va. Contact: William M. McLin, Ex-

ecutive Vice-President, 4351 Garden City Drive, Landover, MD 20785; 301-459-3700.

September 23, annual meeting, American Board of Medical Specialties, Chicago. Contact: Donald G. Langsley, M.D., Executive Vice-President, One Rotary Center, Suite 805, Evanston, IL 60201; 708-491-9091.

September 24-25, annual meeting, American Academy of Medical Administrators, New Orleans. Contact: Thomas H. O'Donovan, Ph.D., President, 30555 Southfield Road, Suite 150, Southfield, MI 48076; 313-540-4310.

September 26-30, biennial international congress, "150 Years of Psychiatry," German Society for Psychiatry and Neurology, University of Cologne. Contact: Dr. Andreas Krah, Oberarzt der Klinik und Poliklinik für Neurologie und Psychiatrie der Universität zu Köln, Joseph Stelzmann Str. 9, 5000 Cologne 41, Germany; (country code) 221-4786357 (tel), (country code) 221-4786398 (fax).

September 27-30, annual meeting, Association of Mental Health Administrators, Cincinnati. Contact: Barbara A. Scott, Executive Director, 60 Revere Drive, Suite 500, Northbrook, IL 60062; 708-480-9626.

September 27-October 1, annual meeting, Royal Australian and New Zealand College of Psychiatrists, Canberra Australian Capital Territory. Contact: Margaret Ettridge, Assistant Registrar, P.O. Box 418, South Carlton, Victoria 3053, Australia; 03-6635466.

September 27-October 1, annual meeting, World Medical Association, Marbella, Spain. Contact: Angel Orozco, Executive Director, 28, Avenue des Alpes, 01210 Ferbet-Voltaire, France; 50-40-75-75.

September 30-October 4, annual meeting, Southern Psychiatric Association, Hot Springs, Va. Contact: Jeanette Stone, Manager of Affiliated Societies, 35 Lakeshore Dr., Birmingham, AL 35219; 205-945-8903.

OCTOBER

October 1-2, 3rd Annual Cultural Impact Conference, "Effective Interventions With Children, Adolescents, and Young Adults in the Context of Ethnocultural Diversity," Chicago School of Professional Psychology, Chicago. Contact: Sue Kulasingham, 312-786-9443.

Sex With Former Patients Almost Always Unethical

While sexual relationships with patients have been considered unethical since Hippocrates, the broadening of the ethical prohibition about sexual relationships between doctors and former patients with the more recent addition to the APA ethics code (1), which states that a sexual involvement with a former patient is "almost always" unethical, has both clarified and left some ambiguity because of the language. The recent article by Dr. Paul Appelbaum and Linda Jorgenson (2) brought into clearer view some possible areas of ambiguity related to sexual contact after termination. While the APA Ethics Committee saw some possible usefulness in legal settings for an arbitrary time period after which sexual involvement might be permissible, the committee strongly disagreed with the conclusions from an ethical point of view.

A patient enters a therapeutic relationship with a conscious assumption about the doctor-patient covenant, as described by Webb (3). The patient assumes that the doctor will do what is in the patient's best interest, will not harm or will prevent harm to the patient, will not exploit the patient for his or her needs, and will allow the patient as much autonomy as possible. Before entering treatment the patient does not understand or appreciate the presence of unconscious wishes, nor does the doctor understand early on or at times during treatment the nature of his or her countertransference. Although all psychiatrists may not subscribe to this theoretical way of thinking, we can all fundamentally agree on some primary ethical principles that underlie ethical behavior. These include autonomy, beneficence, justice, and honesty. When there is conflict among these principles, as is present when undertaking an ethical analysis of sexual relationships with former patients, a decision must be made in favor of one or another ethical principle if all principles involved cannot be resolved. This is the dilemma in the proposal for an arbitrary time period after termination of treatment for the initiation of a sexual relationship.

Over the past decade APA has suspended or expelled over 113 members, most often for sexual exploitation. Without exception, when complaints of this type have been investigated and the psychiatrist involved admitted to the relationship, there have been no situations in which the relationship was considered ethical, no matter how long after termination of treatment it had begun. Although in the majority of cases the relationship began during or soon after termination, there have been several cases in which the relationship began 1 to several years after termination. These cases demonstrated harm to the "former patient," as judged by the investigation. Appelbaum and Jorgenson report that at the Minneapolis Walk-In Counseling Center, there were about 2,100 cases of therapist-patient sexual contact, with less than 1% in which sexual contact began more than 1 year after termination. A review of that information, however, with Mr. Schoener, who provided the data, indicates that of that small percentage, there were at least some cases in which harm to the patient was documented (G.R. Schoener, December 1991).

To prevent harm can we scientifically differentiate more and less vulnerable patients or those more or less vulnerable because of intensity or duration of treatment?

I think not. Some patients with ostensibly low vulnerability have been harmed. Some patients with low-intensity or very brief treatment can nevertheless harbor incredibly strong conscious, as well as unconscious, feelings or fantasies toward the doctor; these feelings or fantasies can be exploited without the patient's conscious awareness, also resulting in harm. Unfortunately, we do not have a scientifically controlled study with all variables considered, but we do have the collective experience of over 40 years of APA Ethics Committee complaint investigations.

What about patient autonomy? Could there be some patients who enter into a sexual relationship with a psychiatrist with true autonomy (without coercion or manipulation)? The answer is, theoretically, yes. Unfortunately, we have little to rely on other than anecdotal reports of happy marriages or relationships. We have not been able to systematically study those situations, since they are not the subject of complaints or they are community or collegial secrets. Whether these anecdotal reports have an ongoing, potentially detrimental ethical effect by creating an acceptable or rationalized role model needs further exploration.

One ethical dilemma, then, is balancing patient autonomy against potential or actual harm. It is here that the prevention of harm to current or future patients outweighs patient autonomy based on our actual experience.

Is it just to strongly side on prevention of harm to a few patients when there may be individual exceptions? Again, if we hamper one relationship that is an exception, we can be fairly certain that the psychiatrist and former patient can find relationships elsewhere. The harmed patient, however, may never again be able to trust in a reparative therapeutic relationship. Therefore, there is some argument for justice over autonomy in the strong prohibition.

Another ethical problem is balancing beneficence and honesty. If there were an arbitrary time period, patients would have to be informed of this possibility before the beginning of treatment. While wanting to do good and prevent harm, we would need to explain that we know that some patients who enter into relationships after 1 year *are* harmed. We would also need to inform the patient if, in our individual case, we would be open to the possibility of a relationship with the safeguards outlined by Appelbaum and Jorgenson. To imagine this discussion borders on the ludicrous, and it would seriously impair any psychodynamic therapy and might well impair other modalities of medical psychotherapy as well (although possibly in more unspoken or unexplored ways). In other words, it would be very difficult, if not impossible, to be completely honest without interfering in harmful ways in the psychotherapeutic process.

A further ethical problem would ensue by setting up a prospective experiment to determine whether an arbitrary time limit makes sense scientifically and ethically. Since we know that some patients have been harmed even after a longer period of noncontact, and without an adequate way to measure "real terminations" or whether transference really diminishes enough to ensure autonomy, this seems particularly hazardous to those experimental patients. We are interested in hearing from our colleagues who have had relationships with former patients and believe there was no ethical problem. While we can understand that the privacy of these situations may cause some reluctance to disclose them, this would at least provide some information (although retrospectively) and would not create or support another possible group of harmed patients through an experiment. We are also interested in hearing from patients who do not feel that they were harmed after a sexual relationship with their psychiatrist following termination. A comprehensive clinical interview by psychiatrists well trained in this area of ethics could help us to understand if there are many exceptions to the very restrictive ethical position and would permit an ongoing, although not strictly scientific, exploration into this discussion.

There is a further ethical duty to the integrity of the profession. With our current knowledge of possible patient harm and the necessity of the public's trust in the profession as a whole, we must resolve the dilemma in favor of the "almost always" position without any arbitrary time period.

The ethics of APA "are not laws but standards of conduct which define the essentials of honorable behavior for the physician." The foreword to *Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry* (1) states, "The annotations are not designed as absolutes and will be revised from time to time so as to

be applicable to current practice and problems." As in all ethics complaints, under our procedures a member accused of any unethical behavior has the right before a panel of peers to argue why in his or her particular case the behavior was not unethical. The multiple levels of review provided give the accused psychiatrist ample opportunity to defend his or her position up to the appeals process. It is this peer process that is the final feedback to a member about how any behavior might be judged.

After this ethical analysis, however, we are left with the point raised by Appelbaum and Jorgenson that a more precise definition of the ethical standard might serve to protect rather than to harm patients. This is where we all agree. Where we part ways, however, is the means to that end. The "almost always" position has achieved some of the protection we wanted.

Should the annotations be clarified by the more definitive position that "sexual relationships with current or former patients are unethical"? For many of the arguments delineated here, my opinion and the opinion of many of us would be yes, again, with the understanding that the annotations are not absolutes and there may be exceptions both theoretically and actually. This suggestion should engender lively debate, as it will.

The APA Ethics Committee, the Board of Trustees, and the Assembly have all agreed that members are bound by our ethics as published. Current and future patients must be able to trust that their psychiatrist's dedication is solely for their welfare in order for treatment to succeed, and an arbitrary time period would weaken that trust. APA members must be able to trust that their Association's ethics annotations and procedures are fair in order to accept them. The real meaning of the current "almost always" position from an ethical point of view ought to be so strong that a proscription against sexual contact with current or former patients should presumptively be accepted when a psychiatrist becomes a member of APA.

The Search: Body, Mind, and Human Purpose

Daniel X. Freedman, M.D.

Psychiatry's appropriate agenda and severe distractions in sustaining it are presently a concern and have historically been so as we struggle with the issues of linking body, mind, and human purpose. Biology requires behaving, variability, and the development of regulations to implement "purpose" in coping with the milieu. Psychiatry begins and ends with our patients—with their diseases and dysfunctions, their biographies and aspirations—which, as a clinical medical science, we must systematically study. Doing that, we will borrow from and pose problems for all the life sciences. New knowledge about how cells and biological systems acquire, code, and exchange information challenges all of medicine. In assessing our advances and future, we consider the history of biological issues in psychiatry and the "sins" of biologism or reductionism. We will see that research questions and strategies in the current study of disease and therapeutics have not fundamentally shifted from Freud and Meyer to modern molecular neurobiology. The tension between the socially conditioned purposive self and impersonal biological processes is an inescapable intrinsic tension for psychiatry of which we must be cognizant as we continue the search.

(Am J Psychiatry 1992; 149:858-866)

In his 1928 APA Presidential address, Adolph Meyer looked back at his 35 years in American psychiatry in order to look ahead (1). His underlying topic was psychiatry's search for an appropriate agenda and distractions in sustaining it. Sixty-three years later, I echo that theme. Arriving from Switzerland as a pathologist, Meyer found psychiatry to be largely "an institutional and legal task." He scolded himself for his dila-

tory discovery of the heart of the matter—the person who is the patient. That, he decided, is where psychiatry and its evidentiary base begins and is its final test. That is the Meyerian integrating idea of professional purpose—the benchmark that can readily elude us absorbed in the pace of progress (or by today's "mismanaged" care). Meyer referred to the "narrowing mind-shy and man-shy" mechanistic philosophy of the nineteenth century as obstructing his vision. Rather than preoccupation with the elements, he sought an integrative and adaptive emphasis on how the behaving parts, when put together, function throughout human life.

As a biologist, he would have agreed with Pascal, who had asked, "If nature is first habit, why is not habit second nature?" Biology, for all its wondrous mechanisms, means adaptive behaving and, inescapably—in the human—mentation. So both biology and mind mattered when Meyer focused on objectifiable behaviors, on habit and personality patterns. Further, he would concur with the emerging dynamic physiological thought (epitomized by Claude Bernard), which Freud and many contemporaries in their own ways shared.

Presented as the Adolf Meyer Lecture at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received Sept. 10, 1991; revision received Dec. 27, 1991; accepted Jan. 24, 1992. From the Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine. Address reprint requests to Dr. Freedman, Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, 760 Westwood Plaza, Los Angeles, CA 90024-1759.

Of intrinsic necessity, many words and ideas in this article have appeared in one form or another in the self-citations noted. My purpose was to assemble my current views on the topics selected rather than to stake out territories of original data or thought. I am thus indebted to 50 years of experience with our field, to previous Meyer lecturers, and to colleagues, past and present, who in person or in their writings helped and continue to foster my education.

Thus, developmentally we acquire and structure internal patternings—dynamic stabilizing *and* adaptive regulations—both biological and behavioral. And so for Meyer the term “psychobiological” meant that mental activities integrate and express both our human aims and bodily needs.

One sees him as resisting categorizations, theory, and dogma in favor of tested, carefully chronicled observations. As to our rush to fashion (which seems to me to be a kind of “intellectual ejaculatio praecox”), Meyer repeatedly warned of wishful illusions, of too concrete a belief in our imaginative “stories.” I refer to metapsychology and metapharmacology or “speculative neurobiology,” which, at their very best, provide tentative working hypotheses for but a part of the problems addressed. Meyer’s targets were mechanistic or theoretical preoccupations that omit human strivings. He called this “psychiatry without psychiatry.” As to defining psychiatry he remarked, “I sometimes feel Einstein has to deal with very simple facts as compared to the complex and erratic performance of the human—the happiness and efficiency of which we psychiatrists are concerned” (1). Happiness and efficiency are surely a broad intellectual mandate, but, for Meyer, the patient was the anchor. In sum, Meyer advocated attention to the personal and contextual details of illnesses and an unprejudiced openness to the “facts that count” (a phrase that he repeatedly used). His sermon applies to more than the 1,302 APA members in 1928. Thus, finding and holding the center is, I believe, psychiatry’s intrinsic problem, and we might wonder why.

PSYCHIATRY’S MULTIPLE PERSONALITIES: 1844–2000

First, looking briefly back with all that in mind, we can chronicle organized psychiatry’s journeys through its various incarnations. In 1844 we were convened as the Association of Medical Superintendents of American Institutions of the Insane (14 met in Philadelphia) and the *American Journal of Insanity* was begun; disease was seen as a brain or moral flaw, and a caring asylum practice was ascendant. In 1892 there was a change of name to the American Medico-Psychological Association; and even with this broadened interest when Meyer joined, there were only 245 members.

For academic psychiatry, 1910 was a critical date. For Meyer then built a multidisciplinary research faculty and designed a curriculum at Johns Hopkins University leading a slow trend to today’s university-based psychiatry. “Psychopathic hospitals” and research (some of which Meyer actively helped) were fostered in Boston, Colorado, Iowa, Michigan, and New York State following the models of the Worcester State Hospital and McLean Hospital. Academically led services and research were Meyer’s lifelong pursuit. He also actively encouraged the emerging lay and paraprofessional involvements. He welcomed Freud, taught with the father of behaviorism, Watson, and spent a brief sabbatical with Kraepelin. In essence, he said of all, “I

was not swayed into any idolatry” (1), and he sharply critiqued the explanation of everything by one theory.

The prewar developments that he encouraged, the mental hygiene and child guidance movements, were influential. Walter Cannon in 1915 had provided a psychophysiology for fight and flight. Psychological factors, perceptions, could thus influence both mental and physical pathology, and the psychosomatics of Graves’ disease was soon a lively topic. The psychiatric team’s accessibility and promptness in their wartime interventions with disturbed soldiers were applauded. Thus, in 1921, with 1,001 members, the American Psychiatric Association became our new name, while our 77-year-old journal became the now familiar *American Journal of Psychiatry*.

But a surge of postwar optimism and the contagious hope of prevention were prevalent. Meyer decried the shift from “the outspoken psychoses to . . . supposedly preventive activity and reformed family and sex life . . . material that is difficult to control and evaluate” (1). He observed in 1928 that “popular psychoanalytic propaganda caused a decided shift . . . when genuine psychiatric research had just barely begun” (1). These diversions were strikingly dominant by 1932 (2), but the community-based, psychiatrist-led teams (with psychologists, social workers, and various lay counselors) in clinics that psychiatry and generous mental hygiene fellowships recruited turned competitive. Along with neurologists and endocrinologists, team members engaged in private “mental health” practices. Of a later similar era (3), I noted (turning to the Bible for help) that we gave away our mess of pottage—and ended with a mess!

Community support collapsed in a backlash to excessive promises. Psychiatry in the 1930s also reacted by “remedicalizing.” Between 1932 and 1940 new organic treatments were begun (pentylentetrazol [Metrazol], CO₂, insulin, ECT in 1938, and lobotomies); psychoanalytic training required an M.D.; and specialty boards were instituted—all a counterweight to competition. And in World War II, psychiatry finally became a division equal to surgery and other medical specialties in the military and again received public plaudits. The National Institute of Mental Health (the second institute of the National Institutes of Health) was authorized in 1946, and after 1952 psychiatry was required in the curriculum of all medical schools.

Sanctioned by a new postwar surge of optimism, the 50-minute hour then became ascendant. Its simplest allure was the Freudian tenet that things may not be what they seem, and inquiries into the vicissitudes of self might unlock secrets or provide meaning. It thus engaged doctor and patient on a scale and scope as never before and surely had its excesses. But in spotting the tricks the mind can play when avoidance is at work, in exploring the gap between stated intent and actual performance, and in tracking the persistence of early wish and learning and patterns of expectations during dependency (transference), it provided a legacy for a canier dealing with human behavior (4).

And, as empathic insight and "hype" worked their way through the 1960s, the tonic of optimism was not only old wine in new bottles but in plastic, biodegradable ones! The psychiatrist-led team that had been reborn in the Veterans Administration and general hospitals of the 1950s peaked with the community mental health centers, where a new orgy of "professional role transvestism" (2) began! The escape from disease escalated. The secondary consequences of being ill—"labeling"—were construed as the real issue. The emphasis was on a civil right to be crazy rather than the tragic functional incapacity *not* to be.

But the psychopharmacological therapies were quietly emerging from the 1950s (when APA expanded to 10,000 members). By the 1970s, pharmacotherapeutics loomed as dominant, sparking the purely practical need to reattend to nosology. Biological psychiatry (the term to me is a redundancy) emerged from the mid 1960s and, with new lay support for it, dominated the 1980s. But that decade was more than the old wine of medicalization given the wealth of new and telling biological and clinical facts that count!

And so we come to the twenty-first century. While the competitors of earlier times in fact have truly burgeoned, APA's membership will soon be over 40,000. The 1990s, at least, have been officially—literally *Presidentially*—declared The Decade of the Brain (an appallingly short time if we truly ponder the challenge). Will brain science replace psychiatry? Will yet another professional personality and name change be in the offing? Perhaps the American Association of Brain Sciences? But experts in acronymic acrobatics might do better than the AABS!

PSYCHIATRY'S CENTRAL AGENDA

Now, whether all this to and fro is a part of the natural tides of history and simply a response to evolving discovery and socioeconomic necessities is difficult to determine. Amnesias about intrinsic purpose, about what we serve for, recur in all collectivities chartered for special societal services—the church, the law, the university, or medicine. But psychiatry has a special fuel for some of these oscillations.

Thus, for our forefathers as for us, the core issue is no more or less than the nature of human nature. Psychiatry, then, intrinsically embraces both broad concerns and their pragmatically narrower derivatives, since we deal with impairments in the very psychobiological tools with which humans attend to, express, and effect their personal purposes.

More precisely, there is an underlying complex question actuating psychiatric thought—how mind and body are linked. For we ask how it is that living matter can accommodate the links of bodily function, subjective experience, and overt behavior (5). The search for how the living organism can gain organization and self-possession, let alone generate the perception of an "I" implementing purpose, enlists a wide range of parties

from the humanities to developmental psychobiology. And in the mind of every child and educated adult the image of the causal "I," the mover of events, is variably expressed (6). Questions of mind and body, though embarrassing, cannot be ruled away; they are intrinsic to human thought and recurring and sometimes practical in our work. Thus, for psychiatry, both breadth and focus will inevitably comprise an intrinsic dialectic and tension. Of that fact we must simply take charge.

At a more practical level, we are, as I politely tried to put it (7), concerned both for the "distress of the healthy and the health of the ill"—or, in English, with both mental health and illnesses. We are concerned with normality and pathology, individual dynamics and families, psychosocial processes and molecular sciences, and much more. How, then, do we concretely define our professional purpose and scientific agenda?

Some call us a behavioral science. Some of us rush to be exclusively biological, psychosocial, or psychodynamic and to wear our identity badges. But taking an inventory of this breadth, in cataloging all this as well as our concern with the mind, one does not have a core definition of our function. There is, in brief, an invitation to pretentiousness when we forget what Meyer stressed: psychiatry as one of medicine's progeny deals with the disturbed function and biography of the person who is the patient.

So in our breadth and our borrowings, our defining intellectual business is the study of disease and dysfunction. Thus I have come to define psychiatry as one of medicine's clinical sciences, a part of the family of the life sciences (8, 9). Every clinical science must aggregate and assess the state of the art and knowledge bearing on its diseases. That has never been the prime agenda of the essential contributory disciplines including what is now called the neurosciences. It is, further, an escapist illusion to believe that other disciplines contain and hoard secret treasures that, if we only knocked on the door, would unlock the answers needed for relief of human suffering (9).

When a new perspective or technology or concept is needed, we will, do, and should cross many interdisciplinary bridges, but always with a question in mind and not with the naive hope of rescue (8, 9). Psychiatrists themselves range into fascinating areas—genetics, molecular neurobiology, cultural anthropology, brain imaging, and more. But we cannot all board fleet monorails winging to the future or pursue ivory tower interests, leaving unattended the core issues. Thus, at the heart of the matter, we must study disease and dysfunction.

That study spans the parameters of etiopathology, predisposition, and precipitating factors and seeks the determinants of symptom expression and its cascading consequences. The job of studying the course and outcome of disease is taxing. The critical search for pathophysiology—or the mediating mechanisms—is in its promising infancy but demanding. It requires study of compensatory adaptations to internal psychic barriers, to impaired bioregulatory systems, to conflict-gen-

erating social signals and internal urges—all of which are ultimately manifest as the signs and symptoms of disease. The study of all this, in addition to therapeutics, their mechanisms and efficiency, and systems of care to enhance optimal function, should keep us busy enough.

Finally, the clinical sciences in practice use what I call the clinical process to investigate the individual patient. It has much in common with the logic of investigative research. It is a highly disciplined and sustained process of both personal commitment and investigatory skill and logic. It is a privileged engagement in enhancing human purpose. It is the essence of the medical model (3, 8, 9).

So, if the study and treatment of dysfunction and disease is our mission, how far have we really come, how did we get here, and how should we think about it? Sketching a perspective on that, I hope simply to share a view that provides me with some framework with which to encounter the alluring future as the search goes on. I will thus touch on where we are on etiology, then in therapeutics, and our research strategies. Finally, I sketch some thoughts on our attitudes about human biology in search of human purpose.

ETIOLOGY AND PATHOPHYSIOLOGY IN PERSPECTIVE

In our searches we now face an enticing, not altogether unproductive, new distraction as molecular biology becomes vividly alive in a way our forefathers could barely imagine. In all of medicine, for the bedazzled clinician the sweep and promise of modern science is, in fact, breathtaking. We should be appreciative but not mesmerized. For, in sobriety we will have to determine which of the plethora of science leads to apply practically in the clinic and clinical research. The gap between visions of what may be and application is still huge but narrowing.

Thus, we are witnessing the second revolution of molecular biology, mapping the human genome and tracking which among millions of proteins are key to a myriad of brain mechanisms and cellular regulatory processes—and which, in the service of gene expression, are responsive to signals transduced from the environment. We are now disarticulating the membrane-embedded amine receptors, precisely tracking their genealogy to particular DNA segments. We are deducing the codes of a profusion of Rosetta stones to understand how intracellular, intercellular, and organismic communications are governed as the various neuronal aggregates go about their massively predetermined—yet conditionable—business. The patterning of nature's designs is clearer. From all this and more, if we stick in our thumb we will pull out some plums. But we still have chores ahead.

In psychiatry, taking advantage of what *is* feasible, we should be pleased. We compute electrical signals from human brain and now deduce the regional brain patterns relevant to function or certain patterns of in-

formation processing, and we are imaging the functioning brain. We are diagraming hitherto unimagined cellular transactions induced by drugs and have quasi-receptor-specific drugs to change and probe brain processes as well as to treat. Measuring hormonal and behavioral responses to such probes, we deduce otherwise inaccessible events. Indispensable are the psychometric tools and precise clinical research designs to objectify our treatments and diseases, and we design operationalized manuals for psychotherapies. With positron emission tomography (PET) (10) and magnetic resonance imaging (MRI) (11) we track postnatal brain development over the life cycle, discerning patterns possibly relevant to schizophrenia. We now witness real momentum. In brief, if you have to be ill (and we now soundly know that some of us do), one is far better off being so today than 50 years ago when I first encountered the field.

In perspective, the past held its own wonders. One can imagine the confidence that ECT generated, and we can intuit the sheer gratification in establishing the etiology and prevention of psychiatry's "two Ps," pellagra and paresis. So, in historical glimpses with perspective as the aim, my purpose is not the detail but to grasp the rate of change and the way things are and go with science.

For the paresis story we had to begin by plucking it out of a welter of psychoses. Thus, descriptive psychiatry gained in precision while groping off the mark for cause (dissolute character, "libidinal excess"). The rest of the story illustrates a characteristically long and indirect journey: in 1904 to neuronal pathology (by Kraepelin's colleague, Alzheimer), in 1906 to a quasi-specific Wassermann blood test for disease detection, to identification (by Noguchi and Moore) of the pathogen in brain in 1910, and then in World War I to specific therapeutics. The spirochete was, in effect, finally burned from the brain by Wagner-Jauregg (the only psychiatrist to receive a Nobel Prize) with his fever therapy. Penicillin—one *war later*—then specifically targeted the bug. Yet after that journey (almost too logical compared to others in medicine) we still do not know the exact pathophysiology leading to the characteristic mental symptoms.

For the pellagra story clinical description was simple. Research begins with epidemiology—Joseph Goldberger's tracking in 1914 of the affected in institutions implicating diet (patients but not staff had pellagra). This upset the consensus of two U.S. commissions of an infectious etiology. Rather than poverty per se (also tagged as "causal"), specific dietary elements (eggs, protein, and so forth) were key. Research and therapeutic maneuvers preceded the precise science solution but also punctured some causal myths. Goldberger persistently searched (12) in bold human experimentation (injecting himself with fluids from patients, manipulating diets both to produce and cure pellagra). With an animal model, he generated a specific hypothesis of an amino acid and vitamin deficiency, which, long after his death in 1929, was verified when, in 1937, nicotinic acid was

identified (and the role of dietary tryptophan later clarified as its endogenous precursor). Yet the exact pathophysiology by which but *one* of the various B vitamins leads to such specific symptoms is still unknown.

These two triumphs are the simplest problems among our many diseases. For all the rest, our powerful science has not yet unearthed the causes of, or precise predispositions to, the pathogenic initial disequilibria and the cascade of consequences we recognize as symptomatic disease. Thus, with all our power, we have promises yet to deliver and miles yet to go.

The pharmacotherapies compelled belief that brain chemistry is relevant, either to etiology or at least to repair. We search—but to date there is no clear proof that etiology is so linked. There is ample proof that dysfunction can be *compensated* for, although not necessarily repaired by, drugs. Thus, for all our power to understand synaptic regulations, we are still calibrating precisely where and how brain substances and mechanisms are relevant to the manifestations of disease. We want to know whether brain receptors are different in the diseased patient—as they ought to be. We have truly enticing starts, some secondary pathophysiology, and a high index of suspicion as to genetics, but to be clear: *clinical diagnostically* specific, etiopathological definitions of our diseases remain an ultimate goal.

THERAPEUTICS IN PERSPECTIVE

To telegraphically compress the sweep of the history of therapeutics, I emphasize two points. The first is that over a century ago we were using combined “moral” or supportive therapies and any available somatic therapy that held allure. With refinements in psychosocial and drug treatments, this is still the case. Second, our *current* pharmacotherapeutic armamentarium derives largely from the postwar period to 1966. In the subsequent 25 years, our recent past, we have mainly been fine tuning what we long had in hand. The correct lower neuroleptic dosage range is now being calibrated. There are new uses of old drugs—carbamazepine for mania, monoamine oxidase inhibitors for panic disorder and more, massive thyroxine for rapid cyclers, and other examples. Clozapine and novel antidepressants are not “new” but simply at long last available.

We now search beyond acute treatment for secondary prevention—the prevention of relapse. Brilliant research from the Western Psychiatric Institute and Clinic of the University of Pittsburgh clarifies that recurrent unipolar depression is far more frequent than we have grasped. Changing the sound conventional wisdom that “lower drug dosage and duration is prudent,” researchers find that *sustained* and *high* doses of imipramine are strikingly effective for prevention of relapse over a 3- or 4-year period. Further, specific psychotherapy (interpersonal therapy) enhances the drug effect and, while less potent on its own, has demonstrable efficacy (13).

Perhaps the most unanticipated recent discovery is

the *selective* utility of serotonergic drug therapies—not only for obsessive-compulsive disorder (for which cognitive behavior therapies are useful), but even for peculiar compelled behaviors such as trichotillomania. Now all this is the mark of a thriving and inquiring clinical discipline systematically at work in serving the ill with greater skill. Nevertheless, we have nothing approaching the etiopathological specificity of our two *Ps* in hand. Nor do we have therapeutic specificity. We do not have drugs that are solely antischizophrenic or exclusively specific for only one of the various *DSM-III* disorders. Our treatments are, at best, symptomatic.

Looking ahead, we want predictors to permit a match of therapies for the individual patient. We will design molecules to reduce or treat side effects. The *targets* of drug research may well shift. Beyond axis I diagnoses, we will be looking at particular drug-reactive components of behavior or disease, not unlike the serotonin-mediated dimension of reactivity or diminished impulse control. Negative and positive symptoms of schizophrenia will be approached on the basis of excitatory amino acids and the newer neurocircuitry of glutamate-mediated cortical loops to subcortical gating and filter systems. The number of tools and growing understanding of their targets strikingly improve the odds of serendipitously winning at this roulette.

Yet while we can hope for specificity, we simply do not know if we should. For we do *not* have a fundamental grasp of the limits and costs imposed by the varied ways by which these interconnected brain organizations and their receptor systems work, adapt, and respond. This is fundamental and critical. In brief, in manipulating brain regulatory systems, we do not know how far we can legitimately expect to go.

We unarguably have a variety of drug and behavioral therapeutic options in hand. The reason may not only be ignorance. Rather, it may derive from the way physiologic regulators work and how, in the abundant redundancies of nature, the brain is built to seek and use a variety of significant inputs. Normally, the most effective way to talk to the entire complex of our receptor- and membrane-linked systems is through the symbols and signals that the psychosocial sciences study and that interpersonal transactions comprise (8). How the brain codes and reads those signals is still unclear. It is, however, clear that psychiatric disorder may require new learning or—what is often now undeniable—molecular stabilization of vulnerable mechanisms. Most probably, both are most often needed.

Fundamentally, what we really seek in the way of pharmacologic contributions is to use nature's logic and gain as much drug specificity as the intrinsic system will allow. This logic allows hypothesis testing to tease apart and reveal mechanisms and their links to the “anatomy and physiology” of behaviors and symptoms. Both drugs and endogenous agents (like the endorphins) act as ligands binding at receptors. Accordingly, we will improve on nature and manufacture what I call “ligandomimetics,” based on such logic. Further, in the far future, we will understand exactly what the

products of specific genes are and use them therapeutically. But to decode the myriad of interactions and define the modalities and dimensions through which gene products influence observable behaviors is not yet fully accomplished for even simple nervous systems, neither for Kandel's snails (we do not yet *quite* have an "ego for the escargot"), nor even for single-cell organisms that, as we do, move, approach, and avoid with something like memory as a guide. It makes one wonder if directionality in simple systems is somehow a precursor of intentionality in the human. We do not know.

RESEARCH STRATEGIES IN PERSPECTIVE

So our research proceeds with what is doable, and we race to catch up with what might be. As pleased as we are with these visions, we ought not be too contemptuous of the past. Our forefathers were not dumber than we. They simply were not as well equipped with information. By 1949 life stress and bodily disease was a hot topic. Long-loop feedbacks from brain to the adrenal and back were seen as regulatory well before the short-loop presynaptic and postsynaptic feedbacks were discovered in the 1960s. Work, eventually garnering Nobels, had *already* begun on the prohormones that are now center stage. Corticotropin-releasing hormone is an example. The brain even then was seen as an endocrine-generating and endocrine-responsive organ.

Strategies in hand long before chlorpromazine are quite similar to ours (appendix 1). To pick one central example (point 2), energy hypotheses are now directly studied with PET scans. Claude Bernard actually laid out the basic groundwork for PET and did so in APA's journal, startlingly in 1872 (14) (and also "innocently" observed conditioned responses that Pavlov would rediscover and systematize). Some of the treatments testing energy notions were bizarre, but the underlying thought that linked metabolism and function was not. The biology of the mental patient was inefficient. Mental disease was not a failure of will, but somehow of the energy to be able to deploy attention at will and to stay sturdily and responsively in touch with the environment. Meyer himself characterized his "response dispositions" as "ergasias"—a neologism that captures the sense of momentum and work intrinsic to adaptive performances. Point 4 refers to the search for special biological stigmata to identify disease. We do not yet have the convenient biological markers either specifically to tag a disorder or trace genetically-linked disorders in the pedigrees of our patients, although eye tracking—elegantly identified *before* World War I (15)—is now being so applied in the schizophrenias.

We thus seem to have come far but, perhaps, not as far as our excitement implies. The old research strategies persist. What is biological about psychiatry is not determined by what we measure, nor how we treat, but rather by how we think about what we discover and do (9). In that vein, the clear concept in 1950 was that external or internal signals will activate normally synchro-

nized behavioral and bodily systems and that mental disorders are reflected in some sign of their dysregulation. If there were characteristic differences at steady state, or with challenge, a deviation would provide a lead. Thus, Bernard and others generating nineteenth-century physiologic regulatory theory still underwrite our current momentum.

BIOLOGY AND HUMAN PURPOSE: THE SEARCH

For the last lap of this race, I want to address problems in our attitudes on biology in the search of human purpose. To render specificity to all this, recall that our forefathers sought a brain that could account for behavior, as we now do. I have called the pre-1940 picture of brain "Prometheus Bound"—a switchboard's inflexibility. Discoveries in the 1940s changed that, but the key notion is that the brain is preponderantly built to behave; it is inexorably generating response, "behaving," so to speak, an instant before we can see a behavior. And even if injured, the components are constantly operating. In fact, manic-depressive disease persists after hemispherectomy, and we see drug-responsive vegetative depression after extensive brain damage. No wonder the task of extracting or controlling key mechanisms or finding disease-specific ones is complicated, since the prior state of these ongoing but incompletely defined neuronal operations largely determines the fate of the next input. So we now indeed have a responsive brain but also a set of complexly connected moving targets. This surely complicates deductions of biobehavioral mechanisms with our simple experimental controls. Very basic biobehavioral operations—vigilance, arousal, habituation, sensitization, startle—and more complex ones (e.g., attention, affect, memory) are still not sufficiently dissected for precision in linking brain and behavior.

In a lecture, the title of which has the hubris to refer to human purpose or intentionality, I might as well plunge, dive deep, and speak of the hunt—not for the Red October, but for the commanding and causal "I." As far as I can tell, in all of neurobiology, the hunt has never produced a capture. With Pennfield's depth electrodes in humans, the deciding or decision-making event was not to be found. In recording evoked potentials, the fact of a decision—but not the making of it—is detected. We find the effect but not the command.

What, then, about the juices of the brain—the monoamines? What do *they* signal and control? Now as to the game of what the amines mean, I have spent a professional lifetime either watching it from the bleachers or episodically working on the field. Yet if I closely watch a patient, I cannot normally tell whether the amine levels are up, down, or in between. Of course, there is parkinsonism. But a dopamine depletion of 70% is necessary for symptoms to be visible. Given the right challenge paradigm, we might someday detect, before the clinical fact, that something is amiss. But note that the amine deficit or neuroleptic dopamine block-

FIGURE 1. E. Power Biggs Makes the Music!

BUT: Don't Confuse Peptides or Amines With Music

ade does not force the parkinsonian behavior. Rather, in the absence of dopamine, the ongoing and busy (and multitransmitter-regulated) striatopallidal activity emerges. In the nineteenth century, Hughlings Jackson described precisely this emergence of unchecked lower systems when the brakes are off. One wonders when neural or psychobiological regulators fail whether this in turn "taxes" amine systems to compensate. If so, keen phenomenologic diagnosis does not answer the question.

For our purposes, the question is, what do the amines mean? Do they make something happen? I speak to the point of command or direction. Thus, in the cartoon (figure 1), E. Power Biggs (the superb Yale-based organist whose recordings of Bach from the 1940s on are still valued) strikes the notes and we hear the music. What is going on in the mechanics of the grand console that produces the precision he intends is not visible. To extend this analogy, we cannot confuse the peptides and amine transmitters with the music that E. Power Biggs intends and commands. Assume that the various organ keys are specific drugs and that we therapists were as skilled as Biggs. When we strike the various drug keys we unfortunately will have lost precision. And that is because we let loose a flurry of mediators of

ongoing self-regulating systems. Neither we nor amines command specific behaviors. There, indeed, is a high specificity of the targets of amines, but their effects on biobehavioral operations are modulatory. Their effects are often state dependent. Put an electrode in the hippocampus (as Segal and Bloom did) where norepinephrine mediates the target cells. Now sound an auditory signal, and the effect of added norepinephrine on the hippocampus is inhibitory. Then give the signal value (implying food to come), and the effect now enhances facilitation (16).

The link of LSD to serotonin, where I began in the 1950s, neatly shows such modulatory effects. Serotonin itself is not psychotomimetic. LSD, we find, acts at various serotonin receptor sites, but as an "imposter" (17, 18). It sends signals from the postsynaptic receptor telling other systems there is too much serotonin when, in fact, the drug actually *reduces* serotonin in the synaptic cleft (acting at a nerve-ending autoreceptor to prevent serotonin release). This "deception" miscues a number of interneuronal regulations. But, to our point on what amines do, certain increases of serotonin will buffer LSD effects. And, in rats, with only a 10% depletion of serotonin, four times *less* LSD than is normally required for a "trip" to be triggered now becomes potent. Thus, in general, a "dimension of intensity" (19) is affected by the amines, which are themselves servants, so to speak, of other ongoing processes.

We cannot, then, either in a specific neurone or brain juice find a precise locus to satisfy our convictions of an operative "I." What we interpret as that homunculus is surely the *product* of multiple regulatory equilibria that, in sum, produce deftly adaptive response. I know of no higher mathematics, computer models of intelligence (appendix 1, point 10), or measures yet in hand to compute and capture such high-level integration—and certainly none that direct one to confirmation through experimental studies of living brain.

Our interest in biological regulatory mechanisms is practically linked to behavior. But for this focus we are accused of the sin of "biological determinism." In fact, what is being determined are the limits, capacity, and flexibilities of the intrinsic organizations with which we as physicians must and do ultimately cope. For Bernard, determinism refers to the immediate or determining cause of phenomena. This "differs from fatalism, on which we cannot act . . . [With] search for the causes determining phenomena . . . materialism, spiritualism, inert matter and living matter cease to exist; only phenomena are left, whose conditions we must determine . . . Scientific determinism ceases here; there are only words beyond, which are of course necessary, but which may delude us if we are not constantly on guard against the traps which our minds perpetually set for themselves" (20).

We are also accused of "biologism." Biology is, in a sense, a nuisance; its workings should be so smooth as to permit one to ignore its mischiefs and, of course (given the boundlessness of pride and wish), the slightest hint of *intrinsic* constraints. Professionally, we can-

not ignore biology. I suspect that the underlying fear of critics derives from the concretism and certitude of our pseudoexplanations, the metapharmacologic vision of us, as a superprecise E. Power Biggs, at the grand console of behavior. But, in fact, biology means, indeed provides for, chance. Behavioral biology reminds us that DNA "expects" an environment and *absolutely requires* its cues. DNA's very structure, its blank areas, and self-replications provide for order but also for error, mutability, and chance from conception and forward to the end. We are thus built to behave and have some room to do so innovatively—for better or worse. The brain, like DNA, also has blank spaces and, of necessity, acquires memory and attitudes, constructing a history through time (8). Nature's instructional and expressive designs entail a ceaseless interplay of the seeking and the sought. In embryology we see a nerve seeking a target that signals an interest and in the human, a search for sources signaling nurturance (4, 9). This choreography of the dynamics of behavior in a varying environment is being discovered at every level. That is the design.

Both those uncomfortable with biology and those exaggerating its certitude might note the inexorability of chance and variation intrinsic to biology. Each organism is, in its expressed DNA repertoire, to an extent unique. That means no escape from dealing with disease variations. All biomedicine might forgo the notion of ultimate rigid control of outcome in the name of therapy or prevention. Biological systems, including the behavioral, do not work that way. Nature does not need the visions of omnipotence that console us, neither illusions of mastery nor of the lofty privilege of dismissing its designs (9). If we are biologically centered at the moment, it is not a matter of ideology but because new insights are now feasible. Psychotherapy research is increasingly systematic. Mental operations and relevant neurocircuitry may someday be saliently dissected with improved research tools and designs. Psychiatry from all this will lose neither its mind nor its brain—nor its essential function to search in any realm yielding to probing inquiry.

Another putative sin is that of reductionism. It *can* divert our attention from the person who is the patient or as to why we legitimately ask questions in the first place. But reductionism is also necessary to produce the leads to understand nature's logic. Genetic knowledge has been derived from such banal witnesses as garden peas, fruit flies, fossils, and bacteria. The psychiatrist who studies rats or chopped liver to search for an enzyme is not trying to "rodentomorphize" man nor memorialize mother's cooking (21). We are searching for designs. Our so-called reductionistic clinical pursuits (say, measuring hormones in patients) are pursued with a wealth of evidence that altered biochemistry and internal molecular regulations are reflected not only in cellular changes, but in changes in the integration and control of small or large components of an organ, the functions of which appear to create the links of mind and body (21). We thus are paradoxically condemned

to deal with highly responsive but ultimately totally impersonal biological processes when we assist our patients to find personal purpose (8).

Drugs, in their effects on attention, perception, affective, and cognitive operations, in fact are ultimately influencing rates and rhythms. The heart, one scientist noted, is composed of wires and juices, as is the brain. These regulate heart rate and rhythm and influence the force and efficiency of output. It is probably the same with the brain. We know our drugs are affecting stop and start mechanisms and their thresholds, which in turn change the rate and range of signals through which a nervous system operates (8, 22).

We should not be impatient. After all, we are only daring to decode the messages that multimillenia of evolutionary trial and error have produced. We inherit, as Paul MacLean reminded us in his 1982 Meyer lecture (23), a reptilian and mammalian brain as well as our unique enlarged frontal lobules—perhaps one-third of the distinctively human brain. And if that evolutionary design had intent, it surely can be and has been criticized for its awkward and archaic impositions on our wish and will! Our huge "dictionary of ignorance," in perspective, is thus not surprising. So we must calibrate our expectations as we piece together the various elements of the story. In medicine we usually have *partial* stories. It is a long and jagged trajectory. We cannot always require the eureka-like leap from the unknown to the definitive final answer, even from the current wonders in hand.

Is all this brain and biology psychiatry's business? My answer, of course, is yes. There are currently fantasies that some fictional all-embracing "clinical neuroscience" will totally replace psychiatry. This is another version of what I call "the game of the name." I do not believe that the lions and lambs of neurology, neurosurgery, psychiatry, and molecular neuroscience, peacefully grazing the pastures of brain together, usefully pictures what we must inevitably confront (4, 22). For it is the different *diseases* these clinical sciences are charged to comprehend that pose their *own* agenda of urgent puzzles and needed interventions and hence, the *sequence* of *particular* questions to be posed to the indifferent complexities of nature. The psychiatric patient—our benchmark—presents the problems to which someone must specifically (and comprehensively) attend. It has been noted (22) that if we abolish psychiatry, a race of "psychiatroids" would have to arise to replace us!

And so we search, knowing that every question answered in science generates new ones. When I arrived in California a few years ago, I did not want to consult astrologers and so consulted an old friend (a guru?). I said to Arthur Yuwiler, "We're poised 'twixt pride and perplexity. What will the fate of science be?" He answered: "There are many things we know for certain—but we don't know which are relevant; there are many things we know are relevant—but we don't know for certain what's going on." And that is the way it has been, is, and will be.

The tension between biology and the accurate perception of a socially conditioned but uniquely purposive self will continue. As all living species, we face impersonal forces that in part frame destiny as we seek and assist others in the quest for personal meaning and dignity in this brief transit (8). We cannot disregard nor be intimidated by nature. We can not make the rules for mind and body, nor precisely orchestrate its transactions. We can, however, search, as Meyer did, for "the facts that count." We can, in brief, search to understand "the way things are" rather than what we wish them to be. That is the *key* search. Of such search Bernard (20) noted, "True science suppresses nothing but goes on searching . . . undisturbed in looking straight at things it does not yet understand." The scientist never grasps truth in its wholeness, but rather "significant fragments; and these fragments of universal truth are precisely what constitute science." We are, he said, "never self satisfied, but still continue to strive . . . This is the feeling which Pascal expressed in somewhat paradoxical form, when he said: 'We are in search never of things but of the search for things.'"

Doing just that concretely positions us to know what may *really* be possible. With that in hand, we truly *can* focus on the person and saliently assist in Meyer's goal for psychiatry: to enhance the happiness *and* efficiency of those whose human strivings we are specially privileged to assist.

APPENDIX 1. Research Strategies in Hand Before Chlorpromazine

1. Clinical epidemiology: retrospective, prospective, cross-sectional, and family studies; community "surveys."
2. Energy hypotheses: tests of O₂ and metabolic differences in brain and body.
3. "Models" and psychotoxins: "Is psychosis in the blood?"—make a "measurement search." Activate anxiety or psychosis (mescaline, LSD, stimulants, adrenergic drugs, CO₂).
4. Challenge tests: e.g., histamine and blood pressure in schizophrenia. If a function differs with challenge, then deviations (whether a cause or consequence) provide leads.
5. Hormonal links: hormonal diseases and mental symptoms.
6. Psychobiology of stress, arousal, attention: autonomic and hormonal response to probes: ergotropic and trophotropic imbalances, and so forth. (We still struggle with an old problem.)
7. Brain structure and function: deduced from EEG, neuropathology, pneumoencephalography (now: PET, MRI, and so forth).
8. Cortical-subcortical links: limbic systems, neurobehavioral studies with lesions, and so forth.
9. Theoretical "models" of a brain that can work: Freud, Sherrington, McCullough, Eccles, and others.
10. Concepts of biological "operations": physiologic regulatory theories (Claude Bernard), homeostasis and "hyperexis," cybernetics (information > energy) (now: computers and neural nets, artificial intelligence, chaos theory, "attraction states" or set points, oscillators, holograms, and so forth).

Mania in Late Life: Focus on Age at Onset

Robert C. Young, M.D., and Gerald L. Klerman, M.D.

The authors review current understanding of manic syndromes and bipolar disorders in the elderly, emphasizing the limited number of systematic studies available. Discussion is focused on the validity of late age at onset as a nosologic distinction in geriatric patients. This issue is contrasted with possible age-associated effects on early-onset illness. Data regarding incidence and prevalence in the elderly are assessed, and the high average age at onset of mania is noted. The review cites evidence that relatively low rates of familial affective disorder and increased frequency of certain diseases and drug use are associated with late age at onset. Aspects of psychopathology in the elderly, course of illness, and outcomes including chronicity, mortality, and cognitive impairment/dementia are considered. Management of these elderly patients is briefly discussed, highlighting questions concerning response to lithium salts.

(Am J Psychiatry 1992; 149:867-876)

With the increased longevity of the population and the generally increased acceptance of psychiatric care, clinicians will see increasing numbers of manic elderly patients (1). These cases involve special problems for diagnosis and management. There are many important unresolved issues for research; these include characterization of the course and outcome of mania in the elderly.

In geriatric major depression, age at first onset of illness emerges as a heuristically useful distinction (2). This review focuses on the validity of this distinction for manic states and bipolar disorders in elderly patients. The distinction is contrasted with the effects of age on early-onset bipolar disorders.

DIAGNOSIS AND CLASSIFICATION

The Manic Syndrome

A considerable degree of international agreement has been reached concerning the complex of signs and symptoms that constitute the manic syndrome. Several sets of operational criteria for mania and for bipolar illness have been developed. In the United States, these include the criteria of Feighner et al. (3), the Research Diagnostic Criteria (4), and those of DSM-III and its

subsequent revision, DSM-III-R. They are similar to those of the World Health Organization's ICD-10.

Manic syndromes differ in severity. Traditional nomenclature has included at least a distinction between mild (hypomania) (5, 6) and more severe states. DSM-III-R includes three grades of severity. In DSM-III-R, manic states accompanied by delusions or other psychotic features, which are not necessary for the diagnosis, are distinguished from those without such features.

Diagnosis

Bipolar disorder. Most patients with manic syndromes have bipolar affective disorder. This is conceptualized as an idiopathic or functional disorder that meets the conventional requirements for a disease or illness (7).

Organic mood disorder. Some affective syndromes, including mania, may be considered symptomatic, i.e., etiologically linked to certain diseases and drugs (8, 9). In this context, Krauthammer and Klerman (9) used the term "secondary" in the sense in which it is used in general medicine. Such syndromes are an important issue in older patients in particular. In DSM-III-R, manic patients judged to have a disorder that is symptomatic, or secondary in this sense, are categorized as having organic mood disorder, manic.

Schizoaffective disorder. Manic signs and symptoms also characterize patients diagnosed as having schizoaffective disorder. This disorder appears to be related to bipolar illness (6). Schizoaffective disorder is not frequently diagnosed in the elderly.

Differential Diagnosis

In elderly patients, the differential diagnosis of manic syndrome includes paranoid schizophrenia and related disorders. It also includes dementia and delirium.

Received June 14, 1989; revision received Oct. 23, 1991; accepted Nov. 21, 1991. From the Department of Psychiatry, Cornell University Medical College, New York City, and New York Hospital-Cornell Medical Center, Westchester Division. Address reprint requests to Dr. Young, New York Hospital-Cornell Medical Center, Westchester Division, 21 Bloomingdale Rd., White Plains, NY 10605.

Supported in part by NIMH grant MH-42522.

Dr. Klerman died in April 1992.

TABLE 1. Types of Bipolar Disorder

Type	DSM-III-R Diagnosis	Characteristics	Comment
I	Bipolar disorder	Hospitalization for mania and major depressive episode	
II	Atypical bipolar disorder	Hypomania and major depressive episode	Can become type I with age
III	Cyclothymia	Frequent hypomanic and depressive symptoms	Can become type I or type II with age
IV	Organic mood disorder	Secondary to disease and drugs other than antidepressants	Cases unrelated to drugs of abuse may more often be of late onset
V	Major depressive episode	Family history of bipolar disorder	Can become type I or type II with age
VI	Bipolar disorder	Unipolar mania	Can become type I with age

Manic patients can experience grandiose and persecutory delusional ideation. Paranoid schizophrenic patients and patients with delusional disorders, on the other hand, can manifest excited, agitated behavior, and express grandiose delusional ideas. For such patients, however, obtaining a longitudinal history establishes the chronic nature of their psychotic mental content and the inconsistency of their affective features. In the past, manic patients with psychosis were often misdiagnosed as schizophrenic; for some elderly patients this diagnosis may have erroneously been carried forward.

Manic patients can present with cognitive dysfunction. Both dementia and delirium, on the other hand, may be associated with affective symptoms of a manic kind. These include restlessness, sleep disruption, irritability, lability of affect, and poor social judgment.

Classification of Bipolar Disorder

Subgroups of bipolar disorder based on course and family history have been proposed (6) (table 1). Type I represents patients hospitalized at least once for a manic episode, for whom there is also a history of major depressive episodes. Type II patients are those with both manic and depressive episodes, but the manic episodes have been mild (hypomania) and have not resulted in hospitalization. Type III patients are those with cyclothymic fluctuations in mood without major depression or mania. Type IV patients are those in whom the manic state is associated with illnesses or medications considered to play an etiologic role. Type V patients have histories of major depressive episodes alone but have family histories of bipolar disorder. Type VI patients have histories of mania but no depressive episodes (unipolar mania).

While chronology (3) has been useful as a classification system for major depression in populations of mixed ages, it has been used less for mania and bipolar disorder. In the aged these may be chronologically the

first diagnosable psychiatric syndromes, i.e., they may be "primary" according to the classification of Feighner et al. (3). Mania or bipolar disorder that is chronologically "secondary" (3) or "complicated" (10) has received even less attention in the elderly. Mania complicating a primary degenerative dementia is an example relevant to the elderly population.

Age at Onset

Manic states, like depressive syndromes, can occur throughout the life span. Age at the time of the first episode of illness must be taken into account in studying mania in the elderly, since widely differing longitudinal histories are noted in these patients (11-14). Elderly patients who present with mania may be experiencing the first affective episode, the first manic episode, or a recurrence of episodes that had their onset in young adulthood.

Patients with mania occurring for the first time late in life may or may not have had prior depressive episodes. If there is a history of depressive episodes, they may have been recurrent in early life. Affective illness thus can change polarity in late life. These patients may or may not have a family history of bipolar illness; if they do, they would have been categorized as type V bipolar patients early in life but become type I or type II in old age. The rate at which young adult type VI bipolar patients become type I with advanced age is also open to investigation.

Studies that have examined age at onset of bipolar disorder have differed in the definitions of "early" and "late." In samples of patients of mixed ages, the median age at onset has generally been used as the criterion. It is therefore difficult to relate findings from such studies to geriatric patients.

Krauthammer and Klerman (9) noted that relatively late age at onset (over 40 years in patients of mixed ages) was a characteristic of manic states associated with medical or neurological conditions or drugs. That is, type IV bipolar disorder, or organic mood disorder, manic, is associated with late age at onset.

EPIDEMIOLOGY

Overall, the rates for both the incidence and the prevalence of mania are apparently considerably lower than the rates for depression in the elderly, as they are in younger adults. However, there have been no large-scale community surveys of geriatric populations that would allow the development of accurate, age-adjusted incidence and prevalence rates for mania and/or bipolar disorder. The studies we have, particularly the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) study, have not yet reported on a sufficient number of elderly patients, although in some of the ECA communities, there was oversampling of the elderly (15). Also, the National Institute on Aging has undertaken some community epidemiologic surveys.

Birth cohort effects, reported in affective illness, need to be kept in mind. In relatives of patients with bipolar disorder and schizoaffective disorder, rates of bipolar, schizoaffective, and unipolar disorders were greater in the more recent cohorts (16). Further, in the study sample of the NIMH Collaborative Program on the Psychobiology of Depression, the more recent cohorts of bipolar patients were younger at the onset of illness than the older patient cohorts (17). It has been suggested that in the lithium era, such cohort effects reflect awareness of bipolar diagnosis earlier in a patient's history (18).

Prevalence of Mania in the Elderly

Manic syndromes are relatively common among elderly psychiatric patients. Mania or hypomania is said to constitute 5%–10% of the diagnoses of elderly patients referred for treatment of affective illness (19). Roth (20) studied patients admitted for psychiatric hospitalization after the age of 60 years; 6% in his series had manic episodes. In the series of admissions studied by Yassa et al. (13, 21), 4.9% of the psychiatric patients over the age of 60 years were manic. Prevalence data on the elderly reflect both patients with recurrent early-life illness and patients with late-onset illness.

Kramer et al. (15) did not detect a current manic syndrome in any of 923 ambulatory community residents aged at least 65 years for whom interview data were obtained as part of the ECA study. This finding was subject to methodologic limitations of cooperation and exclusion of symptomatic syndromes (22) and might also have reflected movement of manic patients out of the community.

Milder forms of mania, including hypomanic and cyclothymic states, may be managed in an outpatient setting. These cases will therefore be underrepresented among hospitalized patients, such as the sample of Spicer et al. (23). There are few available data concerning type II and other bipolar variants among the elderly in the community. Reich and associates (personal communication, 1989) have noted a lower prevalence of type II bipolar disorder in relatives over the age of 40 than in younger relatives of probands with affective disorder.

Incidence of Mania in the Elderly

Theoretical interest focuses on whether there is a change in the true incidence of mania with aging. Pending availability of the results of studies we have mentioned, it remains uncertain whether the risk of developing mania increases, decreases, or remains the same with increased age. Wertham (24) reviewed 2,000 cases with regard to age at first hospital admission for mania; he noted a decline in admissions of manic patients over the age of 50. On the basis of these data and her own (25), Clayton (26) concluded that the risk of mania declines, or at least does not increase, with aging. This is consistent with the findings of a retrospective study of hospital inpatients by Loranger and

Levine (27); however, these investigators excluded an unspecified number of elderly patients with medical illnesses that were judged to be possibly contributory to the affective episodes.

In contrast, Spicer et al. (23) reported that when all admissions to National Health Service psychiatric hospitals in England and Wales during a 2-year period were considered, there was an increase in first admissions of manic male patients, but not female patients, who were over 60 years of age. The fact that explicit diagnostic criteria were not cited suggests that some demented or delirious patients or those with organic mood disorders may have been included; also, patients lacking prior depressive episodes might have been excluded. The authors' findings are consistent, however, with a more recent report by Eagles and Whalley (28), which indicated a gradual increase with age in first admissions of manic patients of both sexes to Scottish hospitals—more so for men. This increase was sustained for patients past the age of 70. In both sexes the association with age was weaker for mania than for depression.

A remarkably late age at onset of the first manic episode has been reported in elderly manic patients. It was found to be the fifth and sixth decades in the retrospective studies of Shulman and Post (12), Glasser and Rabins (29), Young and Jain (11), and Stone (14) and the prospective studies of Broadhead and Jacoby (30) and Young et al. (31).

The studies we have cited involved treated populations. There are no data concerning incidence in the general community.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiologic Factors in Late-Onset Illness

Bipolar disorder is at least as strongly associated with hereditary factors as is major depression (32). As in major depression (33), most investigators have found that probands with late-onset bipolar disorder have a lower rate of affective disorder among their relatives than do probands with early onset; this was true in samples of patients of mixed ages (17, 34–36) and of geriatric patients (12, 14, 29). Further, age at onset of illness may breed true (unpublished paper of J.R. DePaulo et al.).

Yassa et al. (21) noted a high rate of recent disruptive life events among 10 geriatric manic inpatients. All of these patients had late-onset illness; no comparison with an early-onset group was attempted, however.

Medical and neurological disorders, drugs used to treat these disorders, and drugs of abuse are associated with cases of mania in which the age at onset is greater than 40 years. In such patients, Krauthammer and Klerman (9) noted a relatively low familial rate of affective disorder. Such cases represent a potentially valuable model for understanding idiopathic cases (8, 37). Comparison with idiopathic cases to test the nosologic validity of organic mood disorder, manic, remains limited to a few retrospective investigations (10,

38, 39) and the follow-forward study of Shulman et al. (40). In this last study, geriatric "secondary" manic patients were at increased risk for both rehospitalization and institutionalization.

Manic inpatients aged 60 years and older with onset of the first manic episode after age 58 had antidepressant pharmacotherapy associated with their index episode more often than did elderly manic patients with onset at an earlier age (41). This retrospective finding suggests that in geriatric patients, later age at onset may be associated with different response to antidepressant drugs. Interestingly, it contrasts with an observation regarding patients of mixed ages by Nasrallah et al. (42) that younger age and earlier age at onset were associated with mania occurring during antidepressant treatment.

Kay et al. (43) and Post (19) have proposed that major depressive episodes with onset in late life reflect distinct pathophysiologies and etiologies and that, in particular, degenerative changes in the brain might play an important etiologic role in such cases. Shulman and Post (12) reported that the onset of manic states in the geriatric age range was associated with clinical evidence of coarse brain diseases, particularly in men. This sex difference was not found by Shulman et al. (40), however. Stone (14) noted evidence of "organic cerebral impairment" among 22 of 92 elderly manic inpatients studied retrospectively; 14 of these demonstrated memory dysfunction.

Normal aging is associated with morphologic brain changes. Computerized tomography, for example, shows that ventricle-brain ratio and cortical sulcal width increase with age (44). Differences in brain morphology between bipolar patients and control subjects have been reported both in younger adults (45, 46) and in the elderly (30, 47). Abnormalities have also been noted with magnetic resonance imaging (MRI) of the brain in elderly patients with mania (48).

Although in patients with late-life depression those with late onset have greater brain imaging abnormalities (49, 50), a relationship between age at onset and brain morphologic abnormalities in mania has not been established (30, 47). The cases studied by McDonald et al. (48) had a late age at onset.

Manic symptoms can occur in the setting of cerebrovascular disease, as well as other focal brain lesions (51). Right-side lesions have been particularly implicated in the pathogenesis of mania (52).

Pathophysiology

Abnormalities in central neurotransmitter function, particularly that of catecholamines and acetylcholine, have been implicated in bipolar disorders. The evidence consists of effects of drugs associated with mania and those used to treat it, as well as laboratory measures reflecting these systems (53, pp. 417-502; 54, 55).

Age. These same neurotransmitter systems are vulnerable to age-associated processes (56). Differences in catecholaminergic metabolite measurements between

older patients with major depression and control subjects are reportedly greater than between younger patients and control subjects (57). Neurotransmitter-related measures in older bipolar or manic patients have not been reported.

Late age at onset. Differences in peripheral neurotransmitter-related enzyme activity (58) and neuroendocrine function (59) between geriatric patients with late-onset major depression and those with early onset have been reported. Differences in such measures between bipolar patients with different ages at onset have apparently not been reported.

PSYCHOPATHOLOGY

Manic Affective Features

The manic syndrome is phenomenologically "positive." That is, the predominant affective signs and symptoms represent acceleration and/or excesses of behavior, mental activity, or emotion. In contrast to depression, these changes may in part run counter to those associated with increased age. Whether clinical detection/identification of manic or hypomanic syndromes in the elderly can be more sensitive and accurate than that of depression has not been studied.

Age. Modification of manic affective features by age-associated processes has been postulated. Post (19) suggested that elderly manic patients less often have typical flight of ideas than do younger patients. Slater and Roth (60) commented that many cases of mania in old age are "relatively mild." According to their experience, euphoria in older manic patients is often not "infectious," and speech and thought lack the typical "sparkle and versatility" and are commonly "threadbare and repetitious"; on the other hand, "hostility and resentment" are often marked.

These descriptions of elderly manic patients were clinical impressions presented tentatively (61) and were not derived from empirical investigation. Further, the distinction between late-onset and early-onset cases was not made.

Among 40 symptomatic inpatients of mixed ages studied prospectively (62), only four of whom were in their seventh decade, examination of Mania Rating Scale scores gave limited support to earlier impressions. A statistically significant negative association between age and scores on the activity-energy item of the Mania Rating Scale was noted. This finding was consistent with the suggestion by Gurland (63) of relative psychomotor slowness in aged patients with various psychiatric syndromes, not only depression. There was a low negative correlation between age and scores on the language-thought disorder item and a nonsignificant negative correlation between age and scores on the sexual interest item.

Similarly, for a group of manic patients aged 60 years and over who were studied prospectively (30), total scores on the Blackburn Scale for manic psychopathology at ad-

mission to the hospital were lower than those for young adult patients. Older patients had lower scores on the religiosity item of the scale; however, other items did not differentiate older and young patients.

In our own prospective work, relationships between age and aspects of psychopathology were noted in preliminary findings (31). Older patients tended to have lower Global Assessment Scale (GAS) scores when symptomatic. For symptomatic manic patients, there were significant positive associations between age and higher scores on the elated mood and impaired insight items of the Mania Rating Scale and negative correlations between age and scores on the initiating and making plans items of the Blackburn Scale. At discharge, there were negative associations between age and scores on the (increased) sexual interest and (abnormal) appearance items of the Mania Rating Scale and on the careless dress and grooming and impulsive items of the Blackburn Scale.

Late age at onset. Information concerning differences in affective features in groups of patients with differing ages at onset of illness is similarly scant. In a retrospective study (11), geriatric manic patients with later onset had lower overall dysfunction rated with the GAS. Another retrospective report (29) noted no such differences in psychopathology between same-age patients with late onset and early onset. Broadhead and Jacoby (30) noted higher average ratings on the happiness and cheerfulness item of the Blackburn Scale for late-onset than for early-onset cases. Preliminary prospective data from our center suggest less residual psychopathology at discharge, as measured by the Blackburn Scale, and greater change in Mania Rating Scale scores among late-onset patients than among elderly early-onset patients, and higher ratings on impaired insight on the Mania Rating Scale at hospital discharge among late-onset patients (31).

Dysphoria and Mixed States

Dysphoric mood and other depressive signs and symptoms are not uncommon in mania. These have received limited investigation in the geriatric population.

Age. Post (19) suggested that older manic patients exhibit concomitant depressive features more often than do younger patients. This suggestion was based on clinical experience.

In the study by Broadhead and Jacoby (30), there were equivalent mixed features in the elderly and the young manic patients. On the other hand, in that study a greater proportion of the elderly manic patients than of the young manic patients suffered a depressive episode after resolution of mania but before hospital discharge; this difference was statistically significant.

Late age at onset. In one preliminary retrospective study (11), later-onset elderly manic patients had more dysphoric mood than did earlier-onset elderly patients. However, Broadhead and Jacoby (30) found no difference in depressive features during the manic episode between late-onset and early-onset elderly manic patients.

Delusions and Other Psychotic Features

Mania is often accompanied by delusional ideation (64). Hallucinations can also occur.

Age. Post (19) stated that compared to younger patients, geriatric manic patients more often have persecutory delusions that are not mood-congruent. This assertion, based on clinical observation, has received little investigation.

A prospective assessment of manic inpatients of mixed ages did not reveal an association between age and the presence or absence of hallucinations and/or delusions (64). Further, evaluation of geriatric manic patients did not reveal differences in psychosis when they were compared to younger adults in the study by Broadhead and Jacoby (30). Preliminary evaluation of our prospectively studied sample revealed a significant negative association between age and ratings on the grandiose delusion item of the Blackburn Scale (31).

Late age at onset. Rosen et al. (65) reported a negative association between psychotic symptoms and late age at onset among bipolar patients of mixed ages. Angst et al. (66) reported that in bipolar patients of mixed ages, those with mood-congruent psychotic features were older at onset than those with mood-incongruent features.

In geriatric patients, a positive association between delusions and late age at onset has been suggested for major depression (67). No such association has been suggested for geriatric manic states (30, 31).

Cognitive Dysfunction

Affective illness states can be associated with both subjective and objective evidence of decreased cognitive performance. This impairment in performance can resolve with remission of the affective state. Although the literature regarding such pseudodementia has focused on depressive syndromes, an important association between reversible cognitive dysfunction and mania has also been cited (5, 19, 60). Disorientation and even delirium (60) have been described in manic patients.

Clinicians have disagreed on the relation between age and cognitive dysfunction in mania. Some have indicated that such dysfunction is particularly important in older patients (19, 60).

Neuropsychological investigations of bipolar patients of mixed ages have found deficits in attention and memory during manic states (68, 69). Cognitive dysfunction has also been reported in treated, remitted bipolar patients of mixed ages (46, 70). Cognitive dysfunction in bipolar patients has been related to history of neurological disorder (71) and to brain morphology on MRI (46).

Age. Savard et al. (70) reported that cognitive performance of bipolar patients in remission who were older than 40 years was significantly poorer than that of control subjects of the same age. Broadhead and Jacoby (30) commented that a greater proportion of elderly than of young manic patients performed in the demented range on the Kendrick neuropsychological

battery. However, they noted a large discrepancy between verbal and performance IQ in both groups. In preliminary findings from our prospective study (31), elderly patients tended to score lower than younger patients on the Mini-Mental State examination at hospital admission and had significantly more impaired Haycox Scale assessments of behavioral competence at both admission and discharge.

Late age at onset. In a preliminary retrospective study of geriatric manic inpatients (11), those who were older than 58 years at the time of the first manic episode more often showed evidence of cognitive dysfunction in routine clinical evaluations when they were acutely symptomatic than did patients with earlier onset. Neuropsychological testing had not been performed, however.

Stone (14) reported that evidence of "cerebral organic impairment" was present in 24% of elderly manic patients and that more than 60% of these patients had memory impairment associated with the manic episode. Cerebral organic impairment was associated with late age at onset.

Broadhead and Jacoby (30) noted no significant difference in neuropsychological test battery results between early- and late-onset elderly manic patients. A tendency for patients with late onset to show more evidence of cerebral organic impairment was not statistically significant.

The strategy of testing cognitive function both during episodes of illness and on follow-up, when patients are in affective remission, is important to future work with elderly patients. It permits retrospective assessment regarding state-dependent versus persistent cognitive dysfunction. Since a greater proportion of elderly depressed patients with "reversible" cognitive dysfunction than those without may develop persistent cognitive dysfunction/dementia on follow-up (72), this issue needs to be examined in manic syndromes of late life.

AFFECTIVE COURSE

Greater age may be associated with differences in the course of illness in geriatric patients. Late onset compared to early onset of illness may also be associated with differences in the course of illness in these patients.

Resolution of the Acute Episode

Early studies by Roth (20) suggested a poorer outcome for elderly patients with bipolar illness than for those with other "functional" disorders. He reported on 28 geriatric inpatients with mania in the pre-lithium era who were studied retrospectively. Of those still living at 2-year follow-up, 65% had remained in the hospital. This was a poorer outcome than that of geriatric depressed patients. As in the case of the depressed patients, however, the manic patients were more often discharged from the hospital during this interval than were demented patients. Dhingra and Rabins (73) commented that the outcome of geriatric mania has im-

proved since the investigations by Roth were carried out; presumably this reflects, in part, modern pharmacotherapy. Stone (14) noted episodes lasting 2–13 years in five of 92 geriatric manic patients.

Age. There is little information on whether the rates of recovery from mania are different for elderly and younger patients. Post (19) stated, on the basis of clinical impressions, that elderly manic patients are particularly slow to regain insight.

Several investigators (24, 74, 75) have noted a positive association between age and duration of the acute manic episode in populations of mixed ages, even though only a limited portion of these patients were elderly. Wertham's 2,000 patients (24) ranged in age up to the eighth decade. In MacDonald's sample (74), 12 of 451 patients were 60 years of age or older, and in Lundquist's sample (75), 11 of 103 manic patients were older than 50 years.

Chronic mania has been associated with increased age (24, 76). Wertham (24) noted that seven patients with manic episodes lasting at least 5 years ranged in age from 31 to 60 years. Henderson and Gillespie (76) noted an association between chronic mania and an age of more than 40 years. Indeed, among Lundquist's patients (75), fewer of those aged more than 40 years (84%) than of younger patients (95%) recovered.

Himmelhoch et al. (77) did not find an effect of age on recovery from mania in 81 patients studied retrospectively, although all were aged 55 years or more. In the prospective study by Broadhead and Jacoby (30), there was no difference in duration of the index manic episode between older patients and a group of younger patients. The reports of Stone (14) and Dhingra and Rabins (73) did not examine age effects.

Late age at onset. In the literature on patients of mixed ages, some reports suggest an association between greater age at onset and greater duration of episode and/or chronicity. However, the design of the studies does not permit differentiation of associations with age at onset from those with age alone. MacDonald's patients (74), as well as Lundquist's (75), were selected on the basis of first psychiatric hospitalization. In Wertham's study (24), four of seven chronic patients were aged 38–60 years at the onset of their illness.

In the geriatric literature, neither the report of Broadhead and Jacoby (30) nor that of Stone (14) indicated differences in duration of episode between late-onset and early-onset geriatric manic patients. In our own preliminary studies (31), as we have noted, patients with late-onset episodes had somewhat less residual symptomatology at discharge than did early-onset elderly patients. Dhingra and Rabins (73) and Shulman et al. (40) did not comment on duration of the index episode in relation to age at onset.

Relapse

Differing factors may be associated with chronicity and relapse in geriatric affective disorders (78). While some data are available on geriatric depression, there

is need for data concerning relapse of mania and bipolar disorder in the elderly. Roth (20) did not assess relapse. Young and Jain (11) noted that over 2–3 years, 23 (58%) of 40 geriatric bipolar patients required rehospitalization.

Age. An association between greater age and shorter intervals between episodes was noted by MacDonald (74) in bipolar patients of mixed ages.

Late age at onset. For patients of various ages with bipolar disorder, an association of shorter intervals between episodes with greater age at onset was noted by Angst et al. (66). Also for patients of mixed ages, Swift (79) reported an association between age greater than 40 at onset of illness and shorter intervals between episodes. The patients studied by MacDonald (74) were first admissions, so greater age at onset cannot be dissociated from greater age as a correlate of shorter intervals between episodes in that report.

Among geriatric patients, Stone (14) reported increased frequency of readmission, over 1-month to 10-year follow-up, for those with histories of previous affective episodes than for those without such a history. On the other hand, Shulman et al. (40) found that an age at onset greater than 55 years predicted decreased time to psychiatric rehospitalization at 3- to 10-year follow-forward. Dhingra and Rabins (73) reported no difference in relapse rate over 5–7 years between early- and late-onset geriatric manic patients.

NONAFFECTIVE OUTCOMES

Specific nonaffective outcomes in geriatric bipolar disorders also need study. Clinical predictors of specific outcomes may differ depending on age at onset of illness as well as on age itself.

Mortality

Severe manic states can be life threatening. Decreased sleep, impaired nutritional status through overactivity and distraction, and decreased compliance with medical regimens all pose a threat to the health of the frail elderly patient. Although deaths from “manic exhaustion” were reported to occur most often among young patients (80), reports such as this have not defined the age distribution of the total patient sample examined. Hypomanic states presumably carry less risk. The incidence of manic exhaustion has apparently been reduced dramatically in the psychopharmacologic era (81).

Suicide is a mechanism for increased mortality that is associated with bipolar disorder and with increased age. This has not been studied prospectively in geriatric patients with bipolar disorder.

The observed mortality rate for elderly bipolar patients appears to be greater than the base rate for this age group in the community (73). In Roth's early study (20), the mortality rate over 2 years following psychiatric hospitalization was 11%; this was lower than that for elderly demented patients but was higher than that for depressed

patients of the same age. There were two deaths among nine patients followed by Yassa et al. for 2 years (21). In the study by Stone (14), the mortality rate over 2 years was 16% for geriatric mania. In the study by Dhingra and Rabins (73), mortality at 5- to 7-year follow-up was 34%; these authors commented that the survival rate was significantly lower than the expected rate calculated from census data. Similarly, Shulman et al. (40) found that the mortality rate of geriatric manic patients exceeded that of geriatric depressed patients.

Age. Mortality among elderly patients has apparently not been compared to that among younger bipolar patients in the same study. There is evidence for greater mortality among bipolar patients of mixed ages—at least among those with medical illness (53, p. 151)—than among the general population.

Late age at onset. Neither the study by Dhingra and Rabins (73) nor that of Shulman et al. (40) detected differences in mortality between geriatric patients with late onset of illness and patients of the same age with early-onset illness. Stone (14) did not comment on this issue.

Cognitive Dysfunction/Dementia

A proportion of elderly manic patients develop cognitive impairment and/or dementia on follow-up. Stone (14) reported that 3% of 92 geriatric patients with mania went on to develop moderate to severe dementia over an average of 3 years of follow-up. Dhingra and Rabins (73) noted that at 5- to 7-year follow-up, 32% of elderly manic patients had Mini-Mental State examination scores in the cognitively impaired range (less than 24), and 20% had been placed in nursing homes. These authors commented that this was greater than the 1%–2% per year incidence of all forms of dementia expected in this age group in the community (82). The rate for geriatric manic patients was not greater than that for geriatric depressed patients, however.

Age. Emergent dementia occurs relatively infrequently in bipolar patients of mixed ages, but it has received limited study as an outcome (46), and then in combined unipolar/bipolar samples. In the study by Astrup et al. (83), less than 5% of patients with affective disorders were clinically demented on 7- to 19-year follow-up. This is lower than the rate for geriatric patients suggested by the data of Dhingra and Rabins (73).

Late age at onset. It is not known whether late-onset manic patients are at greater risk for development of cognitive dysfunction/dementia than early-onset elderly patients. Dhingra and Rabins (73) could not detect differences in cognitive impairment, as assessed by Mini-Mental State scores, between patients with late-onset mania and geriatric patients with early-onset mania at 5- to 7-year follow-up.

TREATMENT

A general discussion of management of mania in the elderly is beyond the scope of this article. The somatic

treatment modalities used are not unique. Lithium salts are the drug of choice.

The optimal use of lithium salts and alternative somatic treatments has not been delineated in this age group. In the elderly, consideration must be given to factors that influence both drug pharmacokinetics and pharmacodynamics (84).

Pharmacokinetics

Lithium is hydrophilic. It is renally eliminated.

Age. Reduced lithium clearance can be associated with increased age (85). The volume of distribution, because of increased fat/lean body mass ratio, may also be reduced. Further, greater age is associated with additional factors, such as diseases and drug treatments, that can affect lithium excretion (84, 85). These changes necessitate use of lower doses of lithium to achieve equivalent plasma levels.

Late age at onset. This factor has not been examined as a correlate of lithium pharmacokinetics. Onset of mania at a late age may be associated with especially high frequency of physical illness and drug treatments. Therefore, pharmacokinetic changes might be especially frequent in such elderly patients.

Toxicity and Acute Pharmacotherapy

The systematic literature concerning acute treatment of geriatric mania consists primarily of retrospective discussions (14, 29, 77). Some have included demented patients (77).

Reports concerning clinical effects of lithium in geriatric patients have focused mainly on lithium toxicity. Some authors (86, 87) have noted that acute toxic symptoms, including delirium, can occur at plasma levels below 1.5 meq/liter in elderly patients.

Age. While there has been speculation that aging of the brain and other organs renders them more sensitive to lithium, there has been inadequate investigation of this issue. Reports that have included old and young patients have generally not involved comparable lithium levels in the two groups. One important exception is the study by Murray et al. (88), in which more tremor was noted at comparable lithium levels in elderly patients. Since the authors did not assess the patients when they were drug free, they were not able to exclude nondrug causes of tremor. A report of a retrospective study by Smith and Helms (89) noted more moderate to severe side effects, but not total side effects, in elderly patients than in younger patients at comparable lithium levels; neurotoxicity in particular was noted in the elderly patients.

Late age at onset. Late onset may be associated with factors such as medical and neurological disorders and drug treatments that, in turn, predispose to lithium toxicity on a pharmacodynamic basis. These issues, as well as the relationship of late-onset illness per se to toxicity remain open to study.

Efficacy of Acute Pharmacotherapy

Many elderly patients with mania are said to respond well to lithium (13, 14, 29). Clinical experience and the small open study by Schaffer and Garvey (90) suggest that lithium levels below 1.0 meq/liter can be effective in some elderly patients. It is not known, however, whether this is true more often in elderly than in young patients. There also has been no systematic evaluation of the relation of lithium concentrations to therapeutic effects in the elderly population.

Age. Studies of populations of mixed ages have generally not evaluated the effects of age or included many elderly patients. A prospective study (62) indicated trends for positive association between age and scores on the residual language-thought disorder and impaired insight items of the Mania Rating Scale at the third week of hospitalization among older patients from a mixed-age sample who were receiving routine pharmacotherapy, including lithium salts. There was a significant negative association between age and change in scores on the activity-energy and language-thought disorder items between the first and third weeks of treatment. Older patients also were hospitalized longer. In the study by Broadhead and Jacoby (30), fewer elderly patients than younger patients were discharged on a regimen of neuroleptics in addition to lithium. Duration of hospitalization was comparable in the two age groups. In our own preliminary prospective studies (31), elderly patients also did not differ from younger patients in duration of hospitalization.

Clinical predictors of acute response to lithium in younger patients (91) have not been studied in the elderly. One retrospective report (77) suggested that elderly manic patients with dementia respond relatively poorly. However, in the experience of Broadhead and Jacoby (30), concurrent dementia did not adversely affect outcome. Shukla et al. (92) reported poor response to lithium treatment in patients of various ages with organic manic disorders. Black et al. (10) also noted poorer response to acute treatment among patients of mixed ages with mania complicated by serious medical conditions or by other primary psychiatric diagnoses.

Late age at onset. Comparison of response to treatment in late-onset and early-onset elderly manic patients has received minimal investigation. Broadhead and Jacoby (30) did not note differences in therapeutic response in relation to age at onset.

In our preliminary prospective data (31), patients did not differ in duration of hospitalization on the basis of age at onset. However, patients with later onset tended to have lower scores on the Mania Rating Scale and the Blackburn Scale at discharge and greater change from admission Mania Rating Scale scores.

Toxicity and Continuation and Maintenance Treatment

Long-term lithium toxicity, including thyroid dysfunction and possible impact on renal function, has not

been examined specifically in the elderly as a group. Its relationship to age at onset of illness also needs study.

Efficacy of Continuation and Maintenance Treatment

The efficacy of lithium continuation and maintenance treatment in geriatric bipolar affective disorder has not been specifically examined. Such studies are particularly needed in the elderly, since the course of illness in this age group may be more difficult than in younger patients.

Age. One recent negative report (93) concerning the relation between ongoing affective morbidity and duration or age at initiation of lithium prophylaxis apparently dealt with a combined unipolar and bipolar sample. These subgroups were not analyzed separately.

Late age at onset. This dimension has not been examined in relation to the therapeutic efficacy of maintenance and continuation treatment in geriatric bipolar disorder.

CONCLUSIONS

Mania occurring for the first time in late life, with or without antecedent depressive episodes, may differ from bipolar illness in young adulthood. Late-life illness may be more heterogeneous. It appears less directly genetically determined. It may reflect, in part, vulnerability acquired through brain changes and disorders associated with aging. On the other hand, age-associated brain changes also may modify early-onset illness.

Studies of mania in the elderly hopefully will contribute to better diagnosis, to safer and more effective acute treatment, and to improved preventive measures. They are also likely to facilitate our understanding of early-life bipolar disorders.

From Nurture to Network: Examining Links Between Perceptions of Parenting Received in Childhood and Social Bonds in Adulthood

Gordon B. Parker, M.D., Ph.D., F.R.A.N.Z.C.P., Elaine A. Barrett, B.A.,
and Ian B. Hickie, M.D., F.R.A.N.Z.C.P.

***Objective:** The authors' goal was to consider the extent to which key characteristics of their parents influence children's later socialization in terms of social networks and intimate relationships and thus to examine whether there is evidence of such continuity. **Data Collection:** The authors reviewed the pertinent literature and then examined studies using a measure of key dimensions of the parenting received in childhood (the Parental Bonding Instrument) as well as measures of adult social networks. **Findings:** The literature review revealed evidence of links (more evident in women) between perceptions of having received uncaring parenting and deficiencies in diffuse social bonds, which could reflect a causal process, a general response bias, or methodological limitations. By contrast, studies using the Parental Bonding Instrument and a specific measure of adult intimate bonds failed to find links between perceptions of parenting received in childhood and the quality of current intimate relationships unless there was extreme deprivation of parental care; in that case, the current intimate relationship was more likely to be rated as uncaring. **Conclusions:** These findings refine the view that early socialization experiences shape and dictate interpersonal relationships in adulthood. Any deficiencies in parent-child relationships, except, perhaps, gross parental deprivation, appear capable of modification by a range of experiences (particularly subsequent interpersonal relationships).*

(Am J Psychiatry 1992; 149:877-885)

The view that early socialization experiences in the family shape and dictate the structure and function of adult interpersonal relationships (ranging from the most intimate to more diffuse social supports) underlies psychoanalytic, object relations, self psychology, and attachment theories (1). Several empirical studies have been undertaken in the last decade examining evidence of such continuity. The findings have been varied, and we anticipate that the debate over continuity versus discontinuity will be a major focus in social psychiatry because of the capacity for etiological and treatment issues to be refined by the process. In this paper, we shall review representative studies and demonstrate contrasting views about the existence of developmental determination of adult interpersonal relationships.

Because both early family influences and adult social support systems are intrinsically broad and nebulous

constructs, some restriction of definition is required. In this paper we examine the proposition that exposure to dysfunctional parenting is associated with negative social bonding in adulthood, as hypothesized by a number of authors (2, 3). Even this limited proposition, however, assumes the relevance of early family influences to all subsequent adult interpersonal relationships, without qualification as to issues such as the number, breadth, and degree of intimacy of different relationships in later life.

Theoretically, dysfunctional parent-child bonding might emerge from ongoing dysfunctional relationships and/or from prolonged or traumatic parent-child separations (e.g., following parental death or divorce). After several decades of research, it remains quite unclear whether parental separation per se predisposes the child to disruption and conflict in adult intimate relationships (4, 5), largely because of the many intervening modifying variables (especially inadequate parenting before and after the actual separation). Thus, we favor a focus on parental function rather than family structure because dysfunctional parent-child attachment is likely to be a more potent pathogenic variable, not only for individuals who experience parental separation but also for those who do not.

Received April 25, 1991; revision received Nov. 13, 1991; accepted Dec. 12, 1991. From the School of Psychiatry, University of New South Wales. Address reprint requests to Professor Parker, Psychiatry Unit, Prince of Wales Hospital, Randwick 2031, Australia.

CONTINUITY THEORISTS

Bowlby, the most prominent of the attachment theorists, proposed a continuity hypothesis broadly suggesting that an individual's experiences with his or her parents strongly influence any later capacity to form affectional bonds. Bowlby (3) suggested that all later interpersonal experiences are evaluated by the individual in terms of their capacity to accentuate or attenuate developmental pathways that result from early child-parent experiences. Until recently, empirical research on attachment has focused almost exclusively on early childhood, but, for Bowlby (6), "attachment behaviour is held to characterize human beings from the cradle to the grave."

By way of mechanisms, Bowlby described "mental models" constructed by the child on the basis of experiences with significant others. These mental models represent composites of expectations and beliefs about the self and the trustworthiness of others: "Whatever expectations are developed during those years tend to persist relatively unchanged throughout the rest of life" (7). Although later attachment experiences may serve to modify such expectations, childhood experiences are viewed as the principal determinants of abnormalities in adult attachments and, consequently, any resultant increase in psychopathology (notably anxiety and depression).

More recent research has taken attachment theory and its predictions beyond early childhood. Main et al. (8) assessed parents' working models of attachment based on retrospective descriptions of their own childhood experiences and the quality of their own child's attachment. Main et al. assigned adults to attachment groups on the basis of the Adult Attachment Interview, in which assessment was dependent on both "ease" and "content" of recall. Parents who were rated as secure in their own childhoods were reported to have secure attachments with their own infants. For Main et al. these effects need not be stable; some parents whose childhood attachments were insecure demonstrated the ability to cognitively work through negative issues, allowing them to become sufficiently secure in their own parenting skills and resulting in an improved capacity to produce secure offspring.

In contrast to the focus of Main et al. on representations of childhood experiences as influences on subjects' own characteristics as parents, Hazan and Shaver (9) focused on subsequent love relationships or adult intimate relationships. They conceptualized romantic love as an attachment process and developed a self-report procedure to differentiate adult attachment styles. Consistent with the authors' hypotheses, adults categorized as insecure (i.e., ambivalent and avoidant) in their most important romantic relationships reported more negative expectations and beliefs about love, histories of shorter romantic relationships, and less favorable descriptions of their childhood relationships with their parents than did adults who were categorized as secure in their most important romantic re-

lationships. Notwithstanding methodological limitations, the studies of Main et al. and Hazan and Shaver support the utility of extending the attachment perspective to the examination of evidence of links between parent-child bonding and subsequent social attachments in adulthood.

KEY DIMENSIONS AND MEASURES OF PARENTING

As suggested, there are immediate and predictable problems in attempting to measure parent-child bonds and attachments, making it difficult to come to firm conclusions about continuity. Assistance emerges from the numerous multivariate studies (10-12) that have refined central constructs underlying parental attitudes and behaviors. The dimension of "care" has been generated consistently as a principal element, and the next most consistently generated dimension is variably termed "overprotection" or "control." Such dimensions appear fundamental and not limited to parental characteristics. Hinde's review (13) indicated that the dimensions of care and control underlie all important interpersonal relationships, be they parent-child, marital, teacher-pupil, or therapist-patient.

In terms of measures of such parental characteristics, Gerlsma et al. (14) recently reviewed 14 factor-analytically derived measures of parental style and concluded that only three met basic psychometric criteria—the Children's Reports of Parental Behaviour Inventory (15), which is completed by children, the Parental Bonding Instrument (11), and an inventory for assessing memories of parental rearing behavior (16). The latter two are completed retrospectively by adults, and all three measure the constructs of parental care and overprotection.

We reviewed studies using the Parental Bonding Instrument because it is the only one of the three measures used in continuity research and because its reliability and validity have been examined extensively and encouragingly. The Parental Bonding Instrument is a 25-item self-report questionnaire asking subjects to rate their parents as they remembered them in their first 16 years. Ratings for maternal and paternal care and overprotection are generated on a 4-point Likert-style scale; parents may be assigned to one of four contrasting styles, the most pathogenic of which is "affectionless control" (low care, high overprotection) (17). The Parental Bonding Instrument is highly reliable and insensitive to the effects of the respondent's mood, and there is considerable support for its validity as a measure of both actual and perceived parenting in studies using family corroborative witnesses, in twin studies, and in those using independent raters (18).

It is likely that anomalies in parental care and overprotection influence the development of children by somewhat differing mechanisms. The dimension of parental care has been central in the formulation of theories of early socialization and is given expression in the concept of attachment. Bowlby (19) felt that secure in-

fant attachment was most likely to follow the infant's experiencing the caregiver as a reliable source of comfort and as responsive, available, and sensitive. Indifference or rejection on the part of the attachment figure is held to be associated with anxious/ambivalent attachment by the infant. Additionally, deficient care is the parental characteristic most frequently imputed as disposing the child to later psychiatric disorder, and consequent low self-esteem is viewed as a central mediating variable (17). Overprotection (as measured by the Parental Bonding Instrument) is not synonymous with excessive care but is a construct reflecting control, intrusion, infantilization, and encouragement of dependency and is held to have its main deleterious effects by slowing or restricting the child's necessary socialization (17).

Studies Linking Parental Bonding Instrument Ratings With Measures of Adult Social Networks

As noted, studies that have attempted to determine links between Parental Bonding Instrument ratings and measures of the adult social network assume connections between very intimate relationships in childhood (parent-child) and a series of adult relationships that vary widely in terms of their significance and perceived intimacy. Their varying saliency may well influence evidence of links, as we will detail.

Our view of social support parallels that advanced by Sarason et al. (20), who went beyond a concept of social support as an "environmental provision," arguing that it may be viewed more appropriately as an individual difference variable, reflecting a perception of being accepted, loved, and valued (20).

Sarason et al. (20) had 251 college students complete the Parental Bonding Instrument as well as the Social Support Questionnaire, a measure of the number of and satisfaction with available support figures. They confirmed hypotheses formulated in accordance with Bowlby's theory of developmental continuity (21): Parental Bonding Instrument care ratings were positively related to Social Support Questionnaire ratings and Parental Bonding Instrument overprotection ratings were inversely related to Social Support Questionnaire ratings. Given the retrospective nature of the study, the students' reports of childhood may have been distorted by their current level of satisfaction, so the researchers applied a "correction factor for optimism." With this adjustment, they found that correlations between Social Support Questionnaire and Parental Bonding Instrument ratings declined minimally and concluded that, although they were unable to rule out the possibility of a recall bias, their findings suggested that a general tendency to evaluate one's own life in negative terms was unlikely. They also concluded that their findings suggested the importance of the quality of parental involvement with children in terms of a child's later sense of "social embeddedness."

Sarason et al. (22) reported three additional studies. In the first, Parental Bonding Instruments completed by 217 undergraduate psychology students were intercor-

related with a number of self-report measures of social support. Parental Bonding Instrument ratings (particularly those for parental care) correlated positively and strongly with ratings on the Social Support Questionnaire, weakly with ratings on the Inventory of Socially Supportive Behaviors (measuring the frequency of receiving supportive behaviors in the past month), and strongly with ratings on the Family Environment Scale (a measure of currently available social support from the family). The strong correlations between Parental Bonding Instrument ratings and ratings on two of the measures in a group of students might suggest that findings were confounded by the fact that the students' parents represented a major part of the students' social networks, thus contributing to or determining the positive associations. Arguing against this interpretation, Sarason et al. reported links between Parental Bonding Instrument care ratings and ratings of the "percentage of confidants" on the Social Network List when parents were excluded as confidants, indicating that subjects who were recipients of higher parental care also had a higher percentage of confidants in their social network.

In their second study with the same group of students, Sarason et al. (22) reported that high ratings on the Social Support Questionnaire, the Interpersonal Support Evaluation List, and the Perceived Social Support (from friends and family) measure were associated strongly with both high parental care and low parental overprotection ratings on the Parental Bonding Instrument for female respondents but with only high parental care ratings for male respondents.

In their third study with the same sample, Sarason et al. (22) interviewed the students about social support issues, using measures such as the Interview Schedule for Social Interactions (23) to assess the availability and adequacy of close, meaningful relationships as well as the extent and adequacy of more extended social support figures. High parental care ratings and low parental overprotection ratings on the Parental Bonding Instrument were consistently linked with ratings of the availability of extended social support figures, but only high parental care ratings on the Parental Bonding Instrument were linked with ratings of the availability of close relationships. Links were not clearly established between Parental Bonding Instrument ratings and perceived adequacy of social support according to either measure.

These several studies undertaken in essentially normal adults suggest links between the type of parenting received in childhood (especially parental care) and several measures of social support. Three broad explanations of those links, central to this review, could be 1) incorporation of parents into both the Parental Bonding Instrument and the social support measures, creating spurious links, 2) a general response bias toward rating all interpersonal relationships positively or negatively, or 3) a true link between the quality of parenting received and current social support levels. Several similar study designs will now be considered in terms of each explanation.

Flaherty and Richman (1) had 211 first-year medical students complete the Parental Bonding Instrument and the 11-item Social Support Network Inventory, which rates availability, instrumental support, emotional support, event-related support, and reciprocity of the "five most important members" in the respondent's social network. Respondents with higher social support ratings gave both parents significantly higher care ratings and their mothers lower overprotection ratings. Recognizing that the original analysis included family members and the "possible overlap of the effects of parents in both the independent and dependent variables," Flaherty and Richman repeated the analyses after excluding all relatives from the social support measure. Higher social support ratings were still associated with significantly higher parental care ratings; the significance of the ratings for maternal care was stronger than that of the ratings for paternal care. The authors concluded that "the capacity to develop adult supportive relationships is affected by the earlier experience of parental warmth." The operation of a response bias was rejected on the basis of failure to find a link between Parental Bonding Instrument overprotection ratings and social support levels.

Parker and Barnett (24) had a sample of 129 women complete the Parental Bonding Instrument and the Interview Schedule for Social Interactions within 3 weeks of hospital discharge after giving birth to their first child. These women again completed the Interview Schedule for Social Interactions 12 months later. The subjects' ratings on the Parental Bonding Instrument of the care they received from their mothers were significantly linked with their ratings of the availability of close, meaningful relationships and the availability of extended social support figures on the Interview Schedule for Social Interactions on both occasions of testing. However, after the subjects' "neuroticism" ratings (suspected as reflecting a plaintive-set response bias) were partialled out, there was a significant link only between their ratings of the maternal care they received and their ratings of the current availability of close relationships.

Flaherty and Richman (1) suggested that their data were "congruent with the psychodynamic assumption that late affective modes of relating are linked to the quality of earlier object relations." The findings of both their study and ours, however, could be explained by some subjects incorporating their mothers in the Interview Schedule for Social Interactions measure. A general response bias is a less likely explanation because links were restricted to maternal characteristics and not evident in the paternal analyses.

Studies Examining Links Between Parental Bonding Instrument Ratings and Measures of Intimate Relationships

Truant et al. (25) examined links between early parent-child relationships and quality of marriage among 124 subjects who consecutively attended a Canadian family medical center. These subjects rated their par-

ents (and other parental figures) on the Parental Bonding Instrument and their spouses on the Locke-Wallace measure of marital quality. Importantly, these subjects' ratings of maternal and paternal care and overprotection on the Parental Bonding Instrument were not significantly linked with their ratings of marital quality. However, consistent and significant correlations were found for selected subgroups. Poor marital quality was linked with low care ratings on the Parental Bonding Instrument in the case of the "least caring parent" (50% fathers, 40% mothers, 10% others) most clearly for female respondents and after the effects of neurotic symptoms were controlled. (Neurotic symptoms were controlled to exclude the influence of a general negative response bias.) For the whole sample, the strongest correlations emerged in the presence of major childhood separation experiences, but correlations were also observed among a subgroup of female subjects who did not have such "risk" factors to marital quality as major separations in childhood, previous marriage, or current or past emotional illness. Truant et al. suggested that the failure to find links between marital quality and perceived mothering and fathering and the finding of such links for the "least caring parent" or parent figure may reflect the greater influence of a negatively perceived relationship than of "the protective influence of a coexisting good relationship." Thus, they held that their results were consistent with an "interactional model," where early childhood experiences can exert an effect on later adult marital quality but are most likely to do so when childhood adversity (e.g., childhood separations) has occurred.

Truant et al. reported that evidence of developmental continuity appeared limited to psychologically well women; it was not readily apparent in men or psychologically unwell women. Although such selectivity is consistent with the study of Sarason et al. (22), it is contrary to the basic tenets of attachment theory. It has been argued that mate selection among men may be more influenced by physical appearance (26); therefore, men may be less influenced by childhood experiences when forming attachment relationships in later life.

The Intimate Bond Measure (27) was developed in a similar way to the Parental Bonding Instrument as a self-report measure of the care and control exerted by the intimate partner, building on Hinde's recognition of the fundamental importance of such care and control to all interpersonal relationships (13). The developmental study of the Intimate Bond Measure (27) and subsequent research (28, 29) have suggested that this instrument has acceptable validity as a measure of actual and perceived characteristics of the intimate partner and that the care scale (but not necessarily the control scale) is insensitive to depressed mood state.

A series of studies have examined links between Parental Bonding Instrument and Intimate Bond Measure ratings, pursuing one of the fundamental aspects of the continuity hypothesis, namely, that levels of perceived parental care and control relate to similar levels of perceived care and control in adult intimate relationships.

Two contrasting explanations of any links have been pursued: 1) that parental characteristics establish a pattern for adult interpersonal relationships and 2) that any links may be spurious because self-report measures are theoretically susceptible to a number of biases whereby subjects may rate relationships under the general influence of positive (e.g., social desirability) and negative (e.g., plaintive set, assign blame) biases. If either positive or negative biases operate, they will create or inflate correlations between Parental Bonding Instrument and Intimate Bond Measure ratings, unless such biases cancel each other out or are specific to only one relationship (the parent or the intimate partner). Thus, statistical links between Parental Bonding Instrument and Intimate Bond Measure ratings might merely reflect the subjects' particular way of judging relationships. We now note those studies examining links between Parental Bonding Instrument and Intimate Bond Measure ratings.

Hickie et al. (28) had 136 depressive patients complete both measures. A correlation matrix showed no link between parental care and partner care ratings (all correlations were less than 0.19), but there were inconsistent and, at best, weak links between parental overprotection and partner control ratings (the highest coefficient was 0.37, in patients with melancholic rather than nonmelancholic disorders). An analysis of a subgroup of depressive patients who gave "very low" parental care ratings (less than 10 for either parent) revealed a greater chance (odds ratio of 3.1 with a 95% confidence interval of 1.5–6.3) of giving their partners very poor care ratings (less than 10).

In a separate study of patients with nonmelancholic depressive disorders only, Hickie et al. (29) studied 69 patients who had been in an intimate relationship with a cohabiting partner for at least 12 months. When Parental Bonding Instrument and Intimate Bond Measure care ratings were correlated, only one significant association was demonstrated: female patients who gave their mothers high care ratings gave their intimate partners lower care ratings ($r = -0.40$). All other Parental Bonding Instrument/Intimate Bond Measure correlations were less than 0.10. Coefficients for Parental Bonding Instrument overprotection and Intimate Bond Measure control ratings were all less than 0.22. Again, when a separate analysis was made of the patients who gave their parents extremely low care ratings, a weak trend was observed for them to give their intimate partners very low current care ratings (odds ratio=1.8) and very low care ratings for the time before they became depressed (odds ratio=2.4). In both of the studies by Hickie et al., although the perception of a current intimate partner as dysfunctional was associated with a greater risk for nonmelancholic depression, there was no apparent link between that risk and adverse attachment experiences in childhood.

In the two studies of Hickie et al. of patients with clinical depression, most of whom were women, the lack of evidence of developmental continuity is consistent with the findings reported by Truant et al. (25) for

psychologically unwell women. Surprisingly, the attachment hypothesis, which was originally conceived as a possible explanation of suggested links between adverse interpersonal experiences in childhood and psychopathology (particularly depression) in adulthood, seems most difficult to substantiate in psychologically distressed groups, perhaps because vulnerability to clinical depression may be established by a variety of developmental pathways.

Brennan and Wamboldt (30) studied 172 adults attending a private medical center in Washington, D.C. They found that Parental Bonding Instrument care and Intimate Bond Measure care ratings achieved correlations of less than 0.02 and that Parental Bonding Instrument overprotection and Intimate Bond Measure control ratings achieved coefficients of 0.23 and 0.12. The studies of Hickie et al. (28, 29) and of Brennan and Wamboldt (30) confirm findings from an earlier study by Parker and Hadzi-Pavlovic (31), undertaken before the Intimate Bond Measure was developed. In that study, 79 women whose mothers had died when the subjects were children rated their fathers and stepmothers on the Parental Bonding Instrument and their husbands on several items assessing marital affection. The correlations of marital affection ratings with parental care ratings achieved coefficients of less than 0.15. Thus, a series of studies have essentially failed to establish general links between the quality of the parenting received in childhood and the quality of adult relationships.

DISCUSSION

It is currently argued that the experience of secure attachment in childhood increases the likelihood of engaging successfully in adult interpersonal relationships, perhaps because the parent-child attachment promotes a sense of self-worth and a healthy "self-reliance" (19). Conversely, the experience of low levels of parental care and the resulting negative parent-child bonding is held to impair the ability to form close confiding relationships as an adult (19). A poor self-concept and low self-esteem have been suggested as central mechanisms in the latter link, exerting their influence by creating a greater vulnerability to life stressors. Insufficient parental care is held as fundamental in establishing any initial vulnerability, and the impact of overprotective parenting on social competence is considered somewhat less pathogenic, but these dysfunctional parental characteristics are apparently more influential than structural aspects such as parental loss per se. Separation from a parent in childhood has been shown not to constitute a risk if it does not lead to poor parental care (32), and this has been detailed in several reviews (33, 34). The present review builds on such findings, examining particularly the relationship between experiences of different levels of care in early childhood and in adult interpersonal relationships to examine whether the continuity versus discontinuity debate can be clarified and refined.

Support for the general continuity proposition that

parent-child bonding is associated with social bonding in adulthood emerges from studies examining links between ratings of the quality of parenting received and more diffuse measures of the adult social network. It appears most prominent in women and those who are psychologically well. In particular, the quality of parental care received (as measured by the Parental Bonding Instrument) has been shown to correlate positively and strongly with several measures of broad social support (including availability of support figures and number of confidants) and satisfaction levels with such support.

Before acceptance of such qualified support for continuity (i.e., that good parental care in childhood, particularly good maternal care, disposes to a wider and more satisfying social network in adulthood), several noncausal links require closer examination. Reported associations could be a direct result of a failure to distinguish parental from adult social relationships in several studies, general response biases in rating interpersonal relationships, and effects of the subject's personality style or temperament (evoking greater parental care and adult social support). Such confounding issues were overcome in several studies. Although a general "satisfaction" response bias may contribute to the findings in part, residual links favor the hypothesis of continuity between earlier parenting and subsequent social networks, although the mechanism of any such continuity remains speculative.

The Parental Bonding Instrument/Intimate Bond Measure research strategy has allowed us to measure the more specific relationship between the parental care received in childhood and current relationships with an intimate partner without the problem of confounding. Surprisingly, neither continuity links nor evidence of response-set biases (which, if present, would have generated links) have been suggested. Studies using the Parental Bonding Instrument/Intimate Bond Measure research strategy are consistent in their lack of support for the continuity model, except in situations of gross deprivation of parental care, when such respondents were also more likely to rate their intimate partner as extremely deficient in care. Notably, these studies have been conducted in clinical rather than in community samples. Although attachment theory would suggest that continuity is most pertinent to clinical subjects, other factors may influence the findings among patients. A response bias may operate whereby patients may deny associations between past and current relationships. Alternatively, those who are distressed may actually evaluate each relationship more clearly and avoid the "halo" effect often observed in psychologically well individuals. Among clinical patients who report high rates of both dysfunctional parenting and dysfunctional current relationships a ceiling effect may operate so that possible associations between Parental Bonding Instrument and Intimate Bond Measure ratings might have been obscured. The present review clearly suggests the benefit of separating intimate from "other" social support relationships when examining possible differential effects.

Central to the present review has been the concept of bonding. Although it may be argued that the terms "bonding" and "attachment" are similar, there are some important differences. Bowlby (19) argued that the infant is born with a biological propensity to seek attachment to a mother figure and that attachment is an "instinctive" process. Bonding, by contrast, is perhaps best viewed as less clearly biologically determined. The regulation of interpersonal distance is subject to more voluntary and cognitive influences. Rutter (35) suggested that there is a difference between the general tendency to seek attachments and the formation of selective bonds that are personal, social, and reciprocal. Implicit in the distinction is the understanding that processes underlying attachment and selective bonding may be different. Attributes of the adult intimate partner are likely to be essential to the bonding process, so that the final relationship reflects not only the past developmental experiences of the subject but also relevant characteristics of the partner. An overly deterministic view of development fails to concede such current partner effects. As illustrated by the risk factor studies with the Intimate Bond Measure (28, 29), a subject with no developmental vulnerabilities who cohabits with a dysfunctional partner may develop the same psychiatric disorder as a subject who reports both past and current relationships as deficient, so that continuity of negative interpersonal relationships is clearly unnecessary, at least to the onset of depressive disorders.

If the continuity hypothesis for broad social attachment in adulthood is not determined by confounding or by response biases, then some clarification may be emerging. Levels of early parental care influence wider diffuse social networks in adulthood but do not necessarily dictate levels of affection or control in the adult intimate relationship—unless there has been gross early deprivation of parental care.

POTENTIAL EXPLANATIONS OF DISCONTINUITY

Failure to find support for the continuity hypothesis in relation to intimate adult relationships does not require (although it may imply) a rejection of the notion of links between past and present interpersonal relationships. Rather, it suggests the need to acknowledge the potential for modification of developmental patterns. Although experience of low levels of parental care might theoretically create a vulnerability to associate with an uncaring adult partner (when not disposing to actual avoidance of close interpersonal links), several factors may act as modifiers. Brown and Harris (36) emphasized the importance of current circumstances in determining the extent of impact of early experiences. In a complex theoretical model, they identified vulnerability factors that function to increase risk in the presence of a provoking agent. The obvious corollary is that, in general, the lower the rate of provoking agents and vulnerability factors, the less likely it is that support for the continuity hypothesis will emerge. Thus, for

Brown and Harris, the perspective is far from being couched in deterministic terms. The impact of any initial difficulty in the parent-child relationship (e.g., a pervasive negative cognitive bias) can be avoided, or the bias corrected, if the person happens to make a secure attachment at some point. Brown and Harris conceded that to a large extent this is a function of luck. Evidence of discontinuity has been well established with the frequent observation that childhood adversity is not always associated with a poor outcome. For instance, Quinton et al. (37) found evidence for a "cycle of transmitted deprivation." They found that although most of the women they studied who were raised in institutions had higher levels of psychosocial dysfunction and were much more likely to be rated as poor parents in adulthood, some of these women were not poor parents, suggesting the operation of mediating factors—even in conditions of extreme adversity.

The protective effects of a positive marital relationship have been well documented. Good marriages have been described as "health protective," functioning to develop and preserve self-esteem as well as buffering against stress (38). Research has suggested that close affectional ties may be instrumental in modifying the effects of earlier parental deprivation (31, 36). In a longitudinal study of women, Caspi and Elder (39) explored the adult sequelae of difficult behavior in childhood. They found evidence of continuity: difficult behavior in childhood was associated with a greater risk of ill-tempered parenting and poor social control in adult life, but this outcome was contingent on marriage to a nonassertive man. Difficult behavior in childhood made it significantly more likely that women would marry nonassertive men, increasing the likelihood of poor social control. If they did not marry nonassertive partners, no such tendency emerged. These findings suggest continuity extending early life experiences to adult relationships, more specifically to spouse selection. Similarly, Vaillant (40) explored the relationship between earlier childhood experiences, marital relationships, and current psychological health in men and noted that marriage seemed to offer men a chance to overcome previous adverse experiences. That spouse characteristics may function both to maintain or ameliorate maladaptive behaviors has important implications for treatment.

The designs of the studies reviewed here have generally required that subjects be currently or recently involved in an intimate relationship, thereby effectively excluding those whose experience of negative parent-child bonding renders them incapable of engaging in adult intimate relations. There is some evidence, however, that those most in need of the support provided by a good marriage may not be able to benefit from it because the ability to form close relationships may itself be impaired by earlier adversity (41). This failure to establish relationships may prevent us from demonstrating evidence of continuity. As already noted, a negative bonding experience may result in the failure to acquire a true sense of self and resilient self-esteem, attributes

promoting coping in later life. This greater vulnerability may result in the avoidance of close relationships for fear of intimacy, failure, and/or rejection.

Bartholomew (42) has identified two forms of adult avoidance of intimacy. First, a "fearful" style, where a conscious desire for social contact is inhibited by fear of its consequences, and, second, a "dismissing" style, characterized by a defensive denial of the need or desire for greater social contact. Such individuals actively avoid situations of intimacy in an effort to preclude the possibility of rejection. As a result, they undermine the chance of establishing satisfying social relationships, which, empirical evidence suggests, may serve to modify considerably any pattern established by difficulties in early parental bonding (39). For Sroufe (43), later outcomes of earlier experience "may be subtle or complex, taking the form of increased vulnerability to certain kinds of stress, for example, or becoming manifest only when the individual attempts to establish intimate adult relationships or engage in parenting." These sentiments were echoed by Rutter (44), who suggested that certain "adult" events may be necessary to the continuity of adversity from childhood. Rutter et al. (45) suggested that a poor marriage may be an essential factor for the adverse effects of institutional rearing and childhood behavior problems to continue into adulthood.

Undoubtedly, the situation is complex. By restricting the present review to studies using the Parental Bonding Instrument, we acknowledge that conclusions remain subject to the limitations that follow from a reliance on self-report measures. In addition to imperfect memory recall, subjects' reports of childhood relationships may have been biased by subsequent adult history and current life satisfaction. However, as noted earlier, studies investigating the psychometric properties of the Parental Bonding Instrument have found support for its validity as a measure of both perceived and actual parenting over time, thus supporting its construct validity. Further, within the context of the present review, controlling for current life satisfaction (20) and partialling out the effects of neuroticism (25) did not significantly alter associations between Parental Bonding Instrument ratings and outcome measures (adult social support and marital quality, respectively). Thus, given that it is never possible to eliminate the possibility of bias emerging from retrospective recall or other sources, evidence suggests that any such contribution to reported associations is slight at best.

CONCLUSIONS

The concept that early socialization experiences shape and dictate interpersonal relationships in adulthood has, until recently, been viewed as an *a priori* issue rather than one to be investigated empirically. Despite methodological concerns, the present review suggests some refinement to the continuity/discontinuity hypothesis and should assist in the essential task of theoretical and empirical elucidation of the mechanisms and

processes that underlie the varied pathways from childhood to adult life (44). We suggest that some specificity is emerging. First, negative parent-child bonding (in particular, low levels of parental care) may dispose to judging social bonding in adulthood negatively, either directly or through shaping mental models. Second, those exposed to extreme deficits in early parental care appear more likely to associate with an uncaring intimate partner (if a relationship is established at all). Any initial vulnerability established under less extreme difficulties in the parent-child relationship appears capable of being modified by later relational experiences with intimate partners and with significant others. This conceptualization, although at odds with Bowlby's initial view of development (19) (in which outcomes were seen as highly dependent) appears consistent with the dynamic concept of development that is the hallmark of Bowlby's more recent writings (3). Research then needs to focus not only on current relationships but also on relational histories. Although quantitative aspects (number of current and sequential relationships) are important, qualitative aspects are probably more important to study because no optimal number of social support figures can be assumed or presumed. We can envisage a continuum of development where support for the continuity model is strongest in early relational experiences and later positive experiences modify any initial vulnerability and, thereby, facilitate a move toward relational competence. Overall, such findings suggest cause for optimism insofar as there appears to be considerable scope for modification of early patterns, an encouraging conclusion for shaping therapeutic and social policy endeavors.

AIDS/HIV Risk Behavior Among the Chronic Mentally Ill

***Objective:** There is growing concern that chronic mentally ill adults living in the community have a high risk for HIV infection. The purpose of this study was to identify risk knowledge, high-risk behaviors, and risk-related encounters of chronic psychiatric outpatients. **Method:** Detailed information on high-risk behaviors and risk-related situations during the past 12 months was collected from 60 outpatients appearing for regular visits at inner-city community mental health clinics. **Results:** Of the 60 outpatients, 37 (62%) had been sexually active during the past year, and 42% of the men and 19% of the women reported multiple sexual contacts and infrequent use of condoms during intercourse. Assessments of the patients' knowledge of AIDS risks revealed substantial deficits in their practical understanding of AIDS and risk reduction measures. Although use of intravenous drugs was uncommon in this group, many subjects reported histories of 1) trading sex for money, drugs, or a place to stay, 2) coercion to engage in unwanted sex, 3) casual sexual encounters, and 4) sexual activity after use of drugs or intoxicants. Twenty percent of the subjects had met their sexual partners on the streets, in parks, or in other public places. One-third had been treated for sexually transmitted diseases other than AIDS. **Conclusions:** These findings underscore the need for AIDS risk assessment, counseling, and prevention programs for the chronic mentally ill.*

(Am J Psychiatry 1992; 149:886-889)

Cases of AIDS have been historically classified in terms of "risk groups," such as homosexual men and intravenous drug users. Although these categorizations are useful for surveillance purposes, overreliance on them can deflect attention from populations that are not traditionally considered high-risk groups but whose behaviors nonetheless place them at high risk for contracting HIV infection. One such population is the chronic mentally ill.

Persons with chronic mental illness living in the community may be at higher than average risk for HIV infection for several reasons. While some individuals with severe psychopathology—especially those who are older, have major depressive disorders, or take psychotropic medications that reduce libido—have low rates of sexual interest or activity (1-3), clinical and descriptive studies have established associations between schizophrenia, bipolar illness, or borderline disorder and hypersexuality, indiscriminant sexual activity, or impulsive sexual behavior (4-9). Even the chronic mentally ill whose disorders are not strongly associated with impulsive or inappropriate sexual behaviors are likely to exhibit problem-solving, planning, and judgment deficits that increase vulnerability to casual, transient, coercive, or exploitative sexual relationships. Related to these characteristics is the difficulty many of the chronic mentally ill have in establishing stable social-sexual relationships and their frequent sharing of living quarters with, or proximity to, others who have similar

TABLE 1. Inaccurate Knowledge of AIDS Risk Behavior Among 60 Chronic Mentally Ill Subjects

True-False Question	Subjects Who Answered Incorrectly	
	N	%
Most people become sick quickly after getting the AIDS virus	32	53
Women can't get AIDS if they only have sex with men	26	43
People who can give you the AIDS virus always look sick	27	45
Men can't get AIDS if they only have sex with women	23	38
Washing after sex stops AIDS	23	38
Only gay (homosexual) men get AIDS	20	33
You must have many sex partners to get AIDS	19	32
Sex with someone who has used injected drugs creates risk for AIDS	17	28
Using condoms (rubbers) can help prevent AIDS	14	23
Unborn babies can get AIDS from their mothers	11	18
You can get the AIDS virus through one sexual contact	9	15

problems and also function marginally. Finally, the urban chronic mentally ill are often concentrated in inner-city neighborhoods with high rates of drug abuse, alcoholism, sexually transmitted disease, and HIV. Thus, the urban environment increases the HIV risk for the chronic mentally ill living in the community.

Over the past several years, a number of reports (3, 10–13) have stressed the need to better address AIDS prevention for psychiatric patient populations. However, to our knowledge there has been little research on risk behavior characteristics of the chronic mentally ill. Baer et al. (14) assessed psychiatric patients' understanding of AIDS risk and found that knowledge deficits were relatively common. In a larger-scale study, Sacks et al. (15) interviewed patients admitted to an acute psychiatric inpatient unit in New York City and found that 20% of the patients were at very high risk because they engaged in unprotected anal intercourse, needle sharing, or intercourse with HIV-infected partners, and a larger proportion reported multiple heterosexual partners. Approximately 6% of the subjects who were tested had positive HIV antibody results.

The purpose of the present study was to more closely investigate the AIDS risk characteristics of a group of chronic mentally ill adults living in the community. In addition to identifying risk knowledge and behaviors, we sought to obtain information on types of high-risk situations encountered by the chronic mentally ill. By identifying these risk characteristics, it will be possible to better develop education and prevention approaches for this population.

METHOD

The study was conducted in early 1991 in inner-city community mental health clinics in Wisconsin. The

population served is primarily urban, chronic mentally ill patients; nearly 70% have diagnoses of schizophrenia or other psychoses, and 85% have histories of prior psychiatric hospitalization. Patients between the ages of 18 and 47 years were recruited for study participation when they came to the clinics for regular follow-up appointments; almost all had primary clinical diagnoses of schizophrenia, affective disorder, or severe borderline personality. Sixty patients (about 80% of all approached) voluntarily participated in the assessment. The patients who did not participate either refused or were acutely psychotic and appeared unable to provide valid responses. Thirty-two were men and 28 were women. The mean age was 35.8 years ($SD=6.7$), the mean education level was 12.3 years ($SD=2.7$), 56 (93%) were unmarried, and 24 (40%) were white, 34 (57%) were African-American, and two (3%) were Hispanic. Thirty-four (57%) lived in apartments, 15 (25%) lived with their families, and the other 11 (18%) lived in boarding or group homes.

Each subject was individually and privately administered a questionnaire involving AIDS risk behavior, knowledge of AIDS risk, and several other risk characteristics. The questionnaire was presented in written form, and subjects with low reading and comprehension levels were assisted by a research staff member, who read the questions aloud, demonstrated how to complete each item, and clarified the meaning of the questions by using vernacular familiar to the subject. To promote candor, no identifying personal characteristics were collected. The assessment required about 30 minutes for most subjects to complete.

Eleven true-false items were used to measure the respondent's practical understanding of risk behavior and risk reduction steps. The scale items, shown in table 1, were adapted from those used in our prior intervention research (16) and previously normed and validated with other populations, including minority adults (17). The items used in the present study were those which tapped knowledge areas believed most pertinent to risk characteristics of this population.

Each subject was asked to report number of same- and different-sex partners, frequency of intercourse, and frequency of condom use in both the preceding 1-month and 12-month periods. The shorter interval was used to provide a brief retrospective sampling period less susceptible to recall error, and the longer period permitted the detection of low-frequency events that may not have occurred in the past month. Each subject also reported whether—in the past month and in the past year—alcohol, marijuana, crack, illicit injected drugs, or illicit pills were used.

To identify situational circumstances related to risk behavior in this population, each subject was asked to indicate whether, in both the preceding month and the past year, he or she had 1) had sex with someone to obtain money, drugs, or a place to stay, 2) had sex with a partner known less than 1 day, 3) had sex after drinking or drug use, 4) had sex with a partner who used intravenous drugs, 5) been pressured to engage in un-

TABLE 2. AIDS Risk Situations Encountered by 60 Chronic Mentally Ill Subjects in the Past Month and Past Year

Risk Situation	Patients Reporting Situation			
	Past Month		Past Year	
	N	%	N	%
Had sex in exchange for money, drugs, or a place to stay	7	12	8	13
Had sex with partner known for less than 1 day	3	5	6	10
Was pressured into unwanted sex	8	13	9	15
Had sex after using alcohol or drugs	9	15	12	20
Was receptive partner in anal intercourse	1	2	2	3
Had sex with a partner who used intravenous drugs	2	3	4	7

wanted sex, or 6) engaged in receptive anal intercourse. In addition, the subjects used a checklist form to indicate locations where they had met sexual partners in the past year.

All subjects were asked whether they ever had been treated for syphilis, gonorrhea, chlamydia, or genital herpes and whether they had been tested for HIV. If tested for HIV, the subject was asked to indicate whether the result was positive or negative. Each subject was asked to rate her or his personal concern about AIDS on a 5-point Likert scale (1=not at all concerned, 5=very concerned).

RESULTS

Knowledge of AIDS Risk Behaviors

Table 1 lists the questions regarding knowledge of AIDS risk behaviors and shows the proportion of subjects who incorrectly answered each question. In contrast to the high knowledge levels found in AIDS risk surveys of the general population (18), there were substantial deficits in risk knowledge among these chronic mentally ill persons. For example, 43% believed that heterosexual women cannot get AIDS and 45% believed that a person's appearance signals whether he or she has HIV infection. Particularly since the true-false format of the questions would yield a 50% correct rate through guessing alone, it is evident that many patients were substantively uninformed about practical aspects of HIV risk reduction.

Sexual Behavior and Substance Use

Of the 60 subjects, the percentages who said they had been sexually active in the past month and past year were 52% (N=31) and 62% (N=37), respectively. The proportions of men who reported they had had multiple sexual partners in the past month and year were 32% (N=10) and 42% (N=13), respectively. Men who were sexually active reported an average of 2.3 (SD=2.2) dif-

ferent female partners in the past month and 13.2 (SD=19.9) different female partners in the past 12 months. Eleven percent of the men who had female partners (N=2) said they also had had homosexual partners in the previous year. Over the preceding year, the men reported using condoms during an average of 18% of all instances of intercourse.

Fewer of the women in the group reported having had multiple partners during the past month and year: 12% (N=3) and 19% (N=5), respectively. However, these sexually active women reported an average of 3.0 (SD=2.9) different male partners in the past month. Condom use during intercourse was reported by few women; in only 12% of all instances of intercourse were condoms used.

Within the total group, in the past year alcohol had been used by 55% of the subjects (N=33), marijuana by 15% (N=9), crack cocaine by 8% (N=5), illicit drugs in pill form by 8% (N=5), and injected drugs by 5% (N=3). Similar proportions reported use of these substances in the past month: alcohol, 54% (N=32); marijuana, 12% (N=7); crack, 5% (N=3); illicit pills, 7% (N=4); intravenous drugs, 2% (N=1).

Risk Situations Encountered

Table 2 lists risk-producing situations and shows the proportions of subjects who reported encountering each in the past month and in the past year. Eighty-three percent of all subjects reported encountering at least one of these risk situations in the past year. Some risk situations were encountered in the past month almost as often as in the past year. When asked where they had met their sexual partners, 20% of the subjects (N=12) indicated that they had met their partners on the street, in parks, or in public places, 18% (N=11) had met them in bars, 10% (N=6) had met them at the mental health centers, and the balance had met their partners through other means, such as introductions by friends.

Sexually Transmitted Diseases, HIV Testing, and Concern About AIDS

Thirty-three percent of all subjects (N=20) reported that they had been diagnosed and treated for syphilis, gonorrhea, chlamydia, or genital herpes. Thus, a substantial number of patients had histories of treatment for sexually transmitted diseases, which is not unexpected in light of the data on their levels of sexual activity. Thirty-three percent also said they had been tested for HIV antibodies; none reported being told the test result was positive, although we do not know the circumstances under which these subjects were tested and we did not perform testing to establish HIV seroprevalence in this research. When asked to indicate personal concern about getting AIDS, 53% of the subjects (N=32) said they were "quite" or "very" concerned, and only 12% (N=7) said they had no concern.

DISCUSSION

The results of this study demonstrate alarmingly high rates of HIV risk behavior in a group of chronic mentally ill adults living in an urban community. Although some individuals were clearly at little risk—38% of the group reported neither sexual activity nor intravenous drug use in the past year—the majority of patients were sexually active, many had multiple sexual partners, and few regularly used condoms. The high frequency of multiple-partner contacts among sexually active men—an average of more than 13 female partners in the past year—was especially striking. For this reason, a history of sexually transmitted disease was also common.

Our findings with these chronic mentally ill patients living in the community confirm those recently reported by Sacks et al. (15) for acutely ill hospitalized psychiatric patients and further highlight several potential areas for preventive intervention. First, chronic psychiatric patients appear to have substantial deficits in practical AIDS risk knowledge that require educational efforts. Second, most patients reported encountering situations that led to high-risk behavior, such as sexual coercion by others, sexual activity after substance use, sexual activity with casual partners, or trading sex for money or a place to stay. These patterns may prove amenable to training in problem solving, assertiveness, and other skills and to other modes of intervention tailored to AIDS risk reduction. Such approaches have proven useful for teaching other types of "community survival" to the chronic mentally ill (19, 20) and also seem promising for AIDS prevention. Finally, these data clearly indicate that chronic psychiatric patients have a high potential vulnerability to HIV infection and argue for careful, routine clinical assessment of AIDS risk behavior in patients living in or being discharged to the community, the development and evaluation of AIDS prevention activities and their incorporation in the programs of both inpatient and outpatient mental health facilities, and consideration of offering HIV antibody counseling and testing to patients at high risk.

This study is preliminary in a number of respects, including its use of a relatively small number of subjects and reliance on self-reports of behavior and history of sexually transmitted diseases. Larger-scale studies are needed to further explore factors related to risk, to better establish the frequency of HIV and other sexually transmitted diseases in this population, and to test interventions aimed at behavior change. In future research it would be useful to examine differences in risk behavior in relation to patient gender and diagnosis in order to better tailor prevention counseling efforts. Growing evidence of the high-risk behaviors of chronic mentally ill persons, the increasing prevalence of HIV and other sexually transmitted diseases in the urban areas where many psychiatric patients live, and the cognitive, social, and emotional characteristics of

this population that increase their vulnerability make prevention efforts both challenging and urgently needed. Research evaluating the impact of individual, group, and community HIV risk reduction interventions for the chronic mentally ill is also now of great importance.

Evidence of Dysfunction of a Prefrontal-Limbic Network in Schizophrenia: A Magnetic Resonance Imaging and Regional Cerebral Blood Flow Study of Discordant Monozygotic Twins

Daniel R. Weinberger, M.D., Karen Faith Berman, M.D.,
Richard Suddath, M.D., and E. Fuller Torrey, M.D.

***Objective:** The authors previously reported that in monozygotic twins discordant for schizophrenia the affected twin almost invariably had a smaller anterior pes hippocampus, measured with magnetic resonance imaging (MRI), and invariably had less regional cerebral blood flow (rCBF) in the dorsolateral prefrontal cortex during performance of the Wisconsin Card Sorting Test. The present study was an investigation of the relationship between hippocampal pathology and prefrontal hypofunction in the same twin pairs. **Method:** Nine pairs of monozygotic twins discordant for schizophrenia underwent MRI scanning for determination of anterior hippocampal volume and xenon-inhalation rCBF testing for determination of prefrontal physiological activation associated with the Wisconsin Card Sorting Test. **Results:** The differences within twin pairs on the MRI and rCBF measures were strongly and selectively correlated. Specifically, the more an affected twin differed from the unaffected twin in left hippocampal volume, the more they differed in prefrontal physiological activation during the Wisconsin Card Sorting Test. In the affected twins as a group, prefrontal activation was strongly related to both left and right hippocampal volume. These relationships were not found in the group of unaffected twins. **Conclusions:** This finding is consistent with the notion that schizophrenia involves pathology of and dysfunction within a widely distributed neocortical-limbic neural network that has been implicated in, among other activities, the performance of cognitive tasks requiring working memory.*

(Am J Psychiatry 1992; 149:890-897)

It is increasingly appreciated that schizophrenia is associated with deficits in various cognitive functions, especially attention, memory, and "executive" functions (1). Although the mechanisms underlying these deficits are uncertain, recent speculation has focused on dysfunction of temporal-limbic and prefrontal brain regions as explanations for at least the deficits in memory and executive functions, respectively. Poor performance on prefrontal-type executive tasks, such as the Wisconsin Card Sorting Test, has been directly linked to physiological hypofunction of the prefrontal cortex in patients with schizophrenia (2-7), and subtle anatomical deviations in anteriomedial temporal lobe

structures implicated in memory processing have been interpreted as a pathological correlate of the impairments on memory tests also manifested by these patients (8-11). Furthermore, our group has reported data suggesting that these neurobiological findings might be related (12), and we have speculated that the heart of the matter is dysfunctional neocortical-limbic connectivity (12-15).

In a recent investigation of sets of monozygotic twins discordant for schizophrenia, we found that the affected twin almost invariably performed worse on memory tests (8) and on the Wisconsin Card Sorting Test (7, 8) than did the unaffected sibling. Moreover, we also found that the affected twin almost invariably had a smaller anterior pes hippocampus (16) and invariably had diminished relative prefrontal activity as reflected in a measure of regional cerebral blood flow (rCBF) during performance of the Wisconsin Card Sorting Test (7). In this investigation we examined the relationship between these putative abnormalities in hippocampal anatomy and prefrontal cortical physiology in this group of monozygotic twins in an effort to test

directly the hypothesis of a dysfunctional neocortical-
limbic network.

METHOD

Subjects

The study group consisted of nine pairs of monozygotic twins discordant for schizophrenia who were recruited as part of a multidimensional study of schizophrenia in monozygotic twins. These nine pairs are all of the discordant twin pairs who had undergone both magnetic resonance imaging (MRI) and rCBF measurement. Characteristics of these twin pairs were described in detail previously (7, 8, 16). In brief, monozygosity was confirmed by analysis of 19 RBC antigens. Psychiatric diagnosis was established by structured diagnostic interview (SCID parts I and II [17]). The affected member of each twin pair fulfilled the *DSM-III-R* criteria for chronic schizophrenia, and the unaffected member had no evidence of major psychopathology and did not fulfill criteria for an axis I psychiatric disorder. Three pairs were women, and six pairs were men; their mean age was 32 years (range, 25–44 years). Each twin pair had been discordant for at least 4 years when the study began and had remained discordant for an additional 3-year follow-up period. The affected twins were all taking antipsychotic medications at the time of the study. They were in excellent general medical health and had no sign of dehydration or malnutrition. They had been screened for major medical problems and for history of noteworthy drug abuse, head trauma, and other neurological problems. The results of rCBF measurements of this group have been reported in detail elsewhere (7). The MRI scans of these subjects were part of a study of a larger group of monozygotic twins discordant for schizophrenia, and the anatomical measurements from the MRI scans have also been reported previously (16).

Magnetic Resonance Imaging

The method for making anatomical measurements from MRI scans has been described in detail elsewhere (16). In brief, we used spin-echo coronal sections weighted for T_1 relaxation time (repetition time=800 msec, echo time=20 msec); the sections were 5-mm-thick contiguous slices parallel to the floor of the fourth ventricle and were acquired with the same 1.5-tesla magnet (General Electric Signa) for each of the subjects. We used an interactive method for outlining structures of interest on digitized images displayed on a computer image analysis system. In the prior anatomical study (16), the volume of the anterior pes hippocampus was the most robust discriminator of affected from unaffected twin and was selected a priori as the anatomical measure of interest for this investigation. This measure was determined by summing the areas of the pes hippocampus in the first four slices posterior to the amygdala, including a slice through the amygdala-hippocam-

pus junction. The volumes of the pes hippocampus on both the right and left sides were determined. To include a hypothetically "neutral" MRI measure (i.e., a measure that did not discriminate affected from unaffected twin), we derived cerebral volume by adding the total cerebral areas in the four slices through the anterior hippocampus. The raw data concerning these measures have been given elsewhere (16).

Regional Cerebral Blood Flow

The method for determining rCBF by xenon inhalation has also been described in detail elsewhere (2, 4, 7). In brief, the procedure involved a 60-second inhalation of a mixture of xenon-133 gas and air followed by 14 minutes of "washout," during which only room air was inhaled. Regional cerebral blood flow was calculated (by using a biexponential model for gray and white matter compartments) from the radioactivity desaturation curves generated by 32 extracranial gamma ray detectors. Each subject underwent three consecutive rCBF procedures separated by approximately 30 minutes and carried out under three different testing conditions. The first measurement was made during an eyes-closed resting condition that served to acclimate the subjects to the testing procedure. The second and third conditions were an automated version of the Wisconsin Card Sorting Test and a simple sensorimotor control task. They were presented in counterbalanced sequence to control for the possibility of an order effect. The control task was designed to serve as a nonspecific sensorimotor baseline activation condition so that rCBF during the Wisconsin Card Sorting Test could be compared with a control value (2). We calculated rCBF as the initial slope, a unitless measure of cortical gray matter perfusion (18). Initial slope values from 32 cortical regions were collapsed into five regions, as previously described (2, 4, 7). The raw rCBF data have been given elsewhere (7).

Statistical Analysis

The purpose of this study was to examine the relationship between anatomical differences in the volume of the pes hippocampus and physiological differences in prefrontal activation during the Wisconsin Card Sorting Test within monozygotic pairs discordant for schizophrenia. To achieve this goal, we selected two measures a priori as those most likely to test the presence of a relationship.

1. For each twin pair an anatomical difference value was computed by subtracting the pes hippocampal volume in the affected twin from the same measure in the unaffected twin. If we assume that the unaffected twin is an ideal subject for comparison with the affected twin in each pair, the within-pair anatomical difference can be taken as a measure of the relative extent of the putative anatomical pathology associated with schizophrenia in the affected twin.

2. For each pair we computed the difference in rCBF activation associated with the Wisconsin Card Sorting

TABLE 1. Within-Pair Differences in MRI Anatomical Measures for Monozygotic Twins Discordant for Schizophrenia

Twin Pair	Age (years)	Sex	Within-Pair Difference in Volume (cm ³) ^a		
			Left Hippocampus	Right Hippocampus	Cerebral Volume Measure
1	38	F	0.35	0.14	-0.6
2	38	F	0.06	-0.02	-5.2
3	33	M	0.14	0.16	-2.2

7	44	M	0.36	0.29	-0.7
8	28	M	0.24	0.08	4.9
9	27	M	0.03	0.13	-1.9

^aVolume in affected twin was subtracted from volume in unaffected twin.

Test. First, each individual's rCBF *activation* related to performance of the Wisconsin Card Sorting Test was determined. This was accomplished by subtracting the rCBF data during the control task from the rCBF data during the Wisconsin Card Sorting Test. This "subtraction" method has become widely accepted as the "gold standard" for isolating behavior-specific regional brain activity during rCBF studies (2, 19). Second, this difference in rCBF "activation" for the affected twin was subtracted from the analogous value for the unaffected twin. This within-pair physiological difference can be taken as a measure of the relative extent of the cognition-linked dorsolateral prefrontal cortical hypofunction in the affected twin.

The correlation of these within-pair differences in left and right pes hippocampal volumes and within-pair differences in rCBF activation was examined by several procedures, both parametric and nonparametric. Simple nonparametric correlations were performed with the Spearman rho test. Because cerebral perfusion is highly intercorrelated across brain regions and the majority of the variance in regional perfusion is accounted for by the level of global brain perfusion (20), correlations, if found, may not reflect an anatomical relationship with cortical neuronal activity that is *uniquely* regional. Alternatively, such correlations may be obscured by the "noise" introduced by global perfusion variance. To account for these possibilities, we performed a partial correlation procedure to address the principal theoretical question of this study, namely, whether and to what extent the MRI data relate to rCBF data (and, by inference, neuronal activity) that are uniquely regional (i.e., not accounted for by whole brain CBF). This approach is analogous to other methods, such as analyses of covariance (20), that attempt to highlight local brain activity by adjusting regional data for the level of global flow, but the partial correlation approach addresses the strength of the relationship between variables rather than differences in means. The procedure involved using linear regression to remove the effect of the differences in whole brain CBF on the

^aRegional cerebral blood flow during a control task was subtracted from rCBF during the Wisconsin Card Sorting Test. The difference value for the affected twin was subtracted from the difference for the unaffected twin. The values shown here are (unitless) initial slope values from 32 cortical regions collapsed into five regions; the raw data have been given elsewhere (7).

regional differences and correlating the residuals with the MRI difference data. This procedure is referred to as a "semipartial correlation" (21). Because of the relatively small number of subjects, the residual rCBF differences and the MRI differences were also subjected to a nonparametric Spearman correlational analysis. The statistical procedures were performed on a mainframe computer with Statistical Analysis System programs (SAS Institute, Cary, N.C.).

RESULTS

The twin pairs' age, sex, and within-pair differences in the anatomical measures are shown in table 1. The within-pair differences in rCBF activation during the Wisconsin Card Sorting Test are shown in table 2. Left hippocampal anatomical differences and rCBF differences correlated for each region (in all cases, $\rho > 0.7$, $p < 0.05$) and for the whole brain ($\rho = 0.82$, $p < 0.01$). No significant rCBF correlations emerged for right hippocampal differences (in all cases, $\rho > 0.15$). As expected, rCBF differences were highly correlated between all regions and with mean whole brain CBF (in all cases, $\rho > 0.90$, $p < 0.001$). Therefore, to statistically remove the variance in rCBF that is accounted for by whole brain blood flow, the partial correlation procedure was performed. With the correlation between the regional perfusion differences and whole brain perfusion differences thus statistically partialled out, only the dorsolateral prefrontal cortical rCBF differences and the left pes hippocampus volume differences remained significantly positively correlated, according to both the parametric and nonparametric analyses (table 3 and figure 1). This correlation suggests that more hippocampal pathology is associated with less prefrontal activation and that almost two-thirds of the residual variation in prefrontal activation is accounted for by this relationship. Nearly significant negative correla-

TABLE 3. Correlations of Within-Pair Differences in Anterior Hippocampal Volume and Residual rCBF Activation During the Wisconsin Card Sorting Test for Monozygotic Twins Discordant for Schizophrenia

Cortical Region	Correlation of Within-Pair Difference in Residual Cortical rCBF Activation and Within-Pair Difference in Hippocampal Volume

^adf=7.

tions were found for both left and right hippocampus and residual parietal flow. This correlation suggests that more hippocampal pathology is associated with greater parietal activation. The results of a test for a relationship between within-pair differences in the cerebral volume measure and residual prefrontal rCBF activation were not significant (Spearman $\rho=0.40$, $p=0.29$; Pearson $r=0.26$, $p=0.50$).

Post hoc correlations were performed to address whether the results depended on the presence of illness per se. In the unaffected twins as a group, there were no significant correlations between pes hippocampal volume and rCBF activation during the Wisconsin Card Sorting Test, either without or with partial correlations ($p>0.2$ in each case). In the affected group, after the partial correlation procedure was performed prefrontal activation correlated strongly with both the left ($\rho=0.75$, $p=0.02$) and right ($\rho=0.82$, $p<0.01$) hippocampus volumes (figure 2), parietal activation correlated inversely with left ($\rho=-0.68$, $p<0.05$) and right ($\rho=-0.65$, $p<0.06$) hippocampus volumes, and no other correlations, including those without partial correlations, approached significance ($p>0.3$ in all cases).

DISCUSSION

In this study of identical twins discordant for schizophrenia, we found that the magnitude of the within-pair difference in the volume of the left anterior pes hippocampus strongly predicted the difference within the same pair in physiological activation of the dorsolateral prefrontal cortex during a cognitive task that normally elicits physiological activation of this prefrontal brain region (2, 4, 6, 22). Specifically, the smaller the hippocampal volume of the affected twin relative to his or her co-twin, the less activation of the dorsolateral prefrontal cortex during performance of the Wisconsin Card Sorting Test. If the unaffected twin in each pair can be regarded as defining "normality" for that pair on each of the experimental measures, then an anatomical "abnormality" of the pes hippocampus is associated with a cognitively linked physiological "abnormality" of the dorsolateral prefrontal cortex in the affected

FIGURE 1. Relation of Within-Pair Difference in Left Hippocampal Volume to Difference in Prefrontal rCBF Activation for Monozygotic Twins Discordant for Schizophrenia^a

^aActivation of rCBF was measured during the Wisconsin Card Sorting Test; whole brain CBF was partialled out. Values represent rank ordering for each variable. Spearman $\rho=0.80$, $p<0.01$.

twin. If the affected twins have the same neurobiological illness as nontwins with schizophrenia, and there is no compelling body of data to indicate the contrary, then this finding adds to the growing body of evidence implicating dysfunction of neocortical-limbic connectivity in patients with this illness.

Although it is tempting to infer a mechanistic relationship from the correlations found in this report (e.g., hippocampal pathology disrupts prefrontal function), such a conclusion is purely speculative and must be viewed with caution. It is possible that the correlation is a reflection of something that affects both the hippocampus and prefrontal cortex independently but in a functionally related manner. For example, there may be pathological changes, either primary or secondary to the illness, in both brain regions, the effects of which

FIGURE 2. Rank Order Correlation Between Hippocampal Volume and Prefrontal rCBF Activation in Affected Monozygotic Twins With Schizophrenia^a

^aActivation of rCBF was measured during the Wisconsin Card Sorting Test; whole brain CBF was partialled out. Values represent rank ordering for each variable. Left hippocampus: Spearman $\rho=0.75$, $p<0.02$; right hippocampus: Spearman $\rho=0.82$, $p<0.01$.

are most apparent when conjoined function from these regions is required. In other words, prefrontal dysfunction may not be a reflection of defective communication with the anteriomedial temporal lobe but a reflection of intrinsic prefrontal pathology. This possibility cannot be excluded. The impact of medication on the affected twin also cannot be ruled out, but this seems an unlikely explanation for the cognitively and regionally specific relationships we found (3, 7, 23).

Regardless of the precise mechanism, the correlations suggest dysfunction within a widely distributed neural network that has been shown in nonhuman primates to be involved in the performance of "working memory" tasks that are analogous in many ways to the Wisconsin Card Sorting Test (24). Goldman-Rakic and Friedman (25) recently used the 2-deoxyglucose autoradiographic technique with rhesus monkeys to demonstrate that performance of working memory tasks results in metabolic activation and coupling of a distributed network comprising the anterior hippocampus, ventral anterior and dorsomedial thalamus, parietal cortex, and dorsolateral prefrontal cortex. Lesion studies (26, 27) and electrophysiological studies (28) of these regions in the monkey have also suggested that they participate as a neural ensemble in the performance of such cognitive tasks. The fact that the anterior hippocampus and dorsolateral prefrontal cortex may normally communicate with each other during the performance of such tasks implies that a defect in one part of this network (e.g., an anatomical deviation in the temporal-limbic component) might have functional implications throughout the network. The results of the present study are consistent with this possibility. The assumptions that the impairment is of a behavior-specific neural network and is associated with schizophrenia per se are supported by several aspects of this study, including the facts that the correlation held only for the activation

associated with the Wisconsin Card Sorting Test and that it was not found in the unaffected twins as a group.

Because of the methodological limitations in our rCBF technique, especially its inability to measure activity beyond the dorsal cortical surface, we were not able to study rCBF in other components of the putative network (e.g., thalamus, limbic cortex). It is interesting, however, that measures of physiological activity in cortical areas not part of the putative network (i.e., lateral temporal, precentral, and parieto-occipital cortices) were not uniquely correlated with the hippocampal anatomical abnormality. By the same token, an anatomical measure not part of the putative network did not predict rCBF within the network. These negative results further attest to the anatomical specificity of the neural systems involved. Although it is doubtful that the dorsolateral prefrontal cortex and anterior hippocampus are functionally coupled only during working memory or that dysfunction of this neural network in schizophrenia affects only working memory, performance of working memory tasks such as the Wisconsin Card Sorting Test appears to be a sensitive probe of the functional integrity of this network in this illness (15, 22).

In addition to a direct correlation of apparent temporal-limbic pathology with malfunction of the dorsolateral prefrontal cortex, an inverse correlation was also found with regional activation of the parietal cortex. This finding is consistent with the data from nonhuman primates implicating the parietal cortex as an important component of the network (25), at least to the extent that the parietal cortex was the only other cortical region that showed a nearly significant correlation with the hippocampal abnormality. However, the fact that the correlation was in the opposite direction from the correlation with the dorsolateral prefrontal cortex is difficult to interpret. It may suggest, as proposed by Mesulam (29), that prefrontal activation inhibits parietal function. We have found some evidence to support this proposal in studies of rCBF during the Wisconsin Card Sorting Test in normal subjects (22) and in some patient groups (30), where prefrontal and parietal cortex activation may be inversely related. However, the data on metabolic activation during working memory tasks in monkeys show increased metabolism in the parietal cortex (25), a finding that might be expected even if the region were inhibited, because inhibitory synaptic activity may be metabolically demanding. This apparent inconsistency notwithstanding, the finding that greater hippocampal pathology relates to greater parietal physiological activation in these patients misses the possibility that while the network may be underactivated prefrontally, it may also be intrinsically disorganized.

The results in this investigation are also consistent with the findings in an earlier study from our group that used a less sensitive anatomical method. We previously reported (12) that cerebral ventricular size on CT scans, a measure that has been found in numerous studies to be greater than normal in patients with schizophrenia (31), also predicted prefrontal rCBF during the Wisconsin Card Sorting Test but not during another task that

did not require working memory. Although the reason for large ventricles in schizophrenia is uncertain, it has been shown in some studies to be correlated with small hippocampal volume (32).

It should be noted that the anatomical component of almost all of the correlations of within-pair differences involved the left hemisphere. The interpretation of this apparent lateralization of the anatomical-physiological correlation is not straightforward. It may mean that dysfunction of the implicated neural network is lateralized, perhaps on the basis of lateralized neuropathology (33). While the neuropathological abnormalities in the brain in schizophrenia are usually bilateral (34), unilateral abnormalities have been reported and typically favor the left hemisphere (33). An alternative explanation for the lateralized correlation in our study is that the Wisconsin Card Sorting Test may have a bias toward activation of the left hemisphere (6, 35) and thus did not recruit (i.e., test) to the same degree the homologous network in the right hemisphere. In the studies of Milner (36) on the effect of cerebral lesions on performance on the Wisconsin Card Sorting Test, left hemisphere insults tended to have a greater effect. The possibility also cannot be excluded that examining the within-pair differences somehow exaggerated an apparent laterality effect. When the data of the affected twins were analyzed separately, the correlations were bilateral. These questions clearly require further investigation and cannot be answered at the present time.

In a previous study (4) we proposed that a possible mechanism of prefrontal hypofunction during the Wisconsin Card Sorting Test in patients with schizophrenia might involve dysfunctional dopaminergic afferentation of the dorsolateral prefrontal cortex. This proposal was based on the finding in a group of patients with schizophrenia of a positive correlation between prefrontal rCBF during the Wisconsin Card Sorting Test and CSF concentrations of homovanillic acid (4), on similar physiology-behavior relationships in patients with Parkinson's disease (37), and on data from nonhuman primates linking prefrontal dopaminergic function to performance on working memory tasks (38, 39). In light of the present report and the suggestion that prefrontal hypofunction during the Wisconsin Card Sorting Test may reflect dysfunction of a wider neural network, a revision of the earlier proposal may be in order. Since there are no dopaminergic pathways that directly (i.e., monosynaptically) link components of the implicated neural system, it is more likely that if dopaminergic function is affected, it is a secondary phenomenon. There are at least two potential mechanisms for this. Anatomical tracing studies in the rat indicate that prefrontal, probably glutamatergic, projection neurons form synapses with midbrain dopaminergic neurons that project back to the prefrontal cortex (40, 41). This finding suggests that the prefrontal cortex can monosynaptically regulate its own dopaminergic afferentation, perhaps as a means of enhancing or focusing cortical activity when it is particularly advantageous to do

so (42). If the prefrontal cortex is hypoactive because of a primary failure of activation of the prefrontal-limbic network, a secondary effect of this hypoactivity might be diminished excitation of dopaminergic afferents from the ventral tegmental area. In other words, if cortical dopaminergic afferent activity is dysfunctional in schizophrenia, it may be a result, not a cause, of prefrontal hypoactivity. An alternative possibility may involve direct glutamatergic projections from anterior hippocampus to dopaminergic neurons in the ventral tegmental area (43). It is conceivable that loss of function in these excitatory projections may be an additional basis for prefrontal dopaminergic afferent hypoactivity. Preliminary studies of temporal-limbic lesions in the rat support these mechanistic explanations (44, 45). By either mechanism, prefrontal dopaminergic dysfunction, although a secondary, rather than primary, pathophysiological condition could still have important implications for prefrontal function (38, 39, 42).

Throughout this century, the study of monozygotic twins discordant for schizophrenia has been a powerful approach to highlighting biological aspects of this illness. For example, data from monozygotic twin studies have established the importance of both genetic and environmental factors in the pathogenesis of schizophrenia. In an earlier twin study, Reveley et al. (46) showed with CT scans that the ventricles of affected twins were larger than those of unaffected twins. In our series of monozygotic twin studies, this approach has enabled us to observe subtle cognitive (8) and anatomical (16) differences within pairs that almost invariably discriminated the affected from the unaffected twin and physiological differences (7) that thus far have invariably made this discrimination. Because of the subtle differences within pairs in each of these measures and the considerable variability found in the normal population on these measures, it is not surprising that such a high degree of discrimination has not been found in studies of nontwin subjects. By the same token, the correlation reported here between a small reduction in size of the anterior hippocampus measured on an MRI scan and a slight diminution in rCBF related to a specific cognitive task may not be found in other groups unless very large numbers of subjects are studied. If this prediction is correct, it raises the question of whether the correlation itself is so rarefied as to be neurobiologically trivial. This possibility can be explored in future studies that address in other ways the integrity of prefrontal-temporal-limbic connectivity. In the meantime, the finding of a statistically strong correlation between abnormal hippocampal morphology and abnormal prefrontal physiology that is in the hypothesized direction (i.e., more abnormality of one predicting more abnormality of the other) and its emergence under very specific conditions (i.e., when both the effect of illness is amplified by a within-pair comparison and the relevant neural system is stressed by a cognitive task that demands function from it) implicate by direct experimental evidence dysfunction of this neural connectivity in the pathophysiology of schizophrenia (47).

Neuropsychological Functioning of First-Episode Schizophreniform Patients

Anne L. Hoff, Ph.D., Henry Riordan, M.A., Donald W. O'Donnell, M.A.,
Laurette Morris, Ph.D., and Lynn E. DeLisi, M.D.

***Objective and Method:** This study compared 32 consecutively admitted first-episode schizophreniform patients, 26 patients with chronic schizophrenia according to the DSM-III-R criteria, and 25 normal comparison subjects on a comprehensive battery of neuropsychological tests to determine the degree of cognitive impairment existing at the onset of schizophrenic illness. Patients were tested within 2 weeks of admission to the hospital, after their medication had been stabilized. **Results:** With age and education controlled, the first-episode and chronic patients performed significantly worse than the normal subjects on neuropsychological summary measures of executive function, verbal memory, spatial memory, concentration/speed, and global cognitive function and on left and right hemisphere function scales. The first-episode patients were as cognitively impaired as the chronic patients on all summary scales and many of the individual tests. Both groups showed relatively greater left than right hemisphere dysfunction. **Conclusions:** These findings suggest that substantial cognitive deficits, comparable to those of chronic patients, are present early in the course of psychotic illness.*

(Am J Psychiatry 1992; 149:898-903)

Neuropsychological research focusing on cognitive deficits in schizophrenia has resulted in several important yet potentially contradictory findings. Studies have shown that chronic patients demonstrate a diffuse pattern of cognitive impairment which is frequently indistinguishable from that of brain-damaged patients (1-3). Some reports have suggested that there is a focal pattern of deficit, such as left hemisphere dysfunction (4-7), frontal lobe impairment (8-10), or dysfunction of the temporal-limbic cortex (8, 11). All of these investigations have included heterogeneous groups of chronic patients at different stages in the course of their illness, with varying histories of medication and numbers of hospitalizations.

Studies of military inductees (12, 13) confirmed that there was a deterioration in cognitive function from premorbid levels (at the time they enlisted in the service) to the onset of illness; however, these patients had al-

ready been diagnosed as schizophrenic for 2-11 years when they were tested after the onset of illness. Longitudinal neuropsychological studies of schizophrenic patients (reviewed by Heaton and Dr  xler [14]), in which testing was done after the onset of illness and at follow-up intervals, have indicated either no change or modest improvement on measures of cognitive function, particularly in patients with a good clinical outcome. A subgroup of chronically hospitalized patients seem to show cognitive deterioration when retested. In most of these studies, patients were tested early in their illness, but not necessarily in their first episode, and at various follow-up intervals. They were also given a limited number of cognitive tests.

Because of these limitations, it is unclear what degree of cognitive dysfunction exists at the onset of schizophrenic illness. This study was designed to determine whether schizophreniform patients would perform worse than normal subjects on many cognitive tasks and, if so, whether their deficits were comparable to those seen in chronic patients.

METHOD

The subjects included 32 first-episode psychotic patients (26 male and six female) consecutively admitted to a university-affiliated state hospital research unit with the *DSM-III-R* diagnosis of schizophreniform disorder (less than 6 months' duration). An additional 26 pa-

Presented at the annual meeting of the American College of Neuropsychopharmacology, Maui, Hawaii, December 10-15, 1989. ^cSignificant difference between A and B ($t = -2.5$, $df = 1$, $p < 0.01$).

tients (16 male and 10 female) with the *DSM-III-R* diagnosis of chronic schizophrenia (12 undifferentiated type, eight paranoid type, four schizoaffective, and two disorganized type) constituted the chronic group. They included consecutive admissions to the same inpatient unit ($N = 17$) and all of the patients from the university day hospital program in the department of psychiatry ($N = 7$) and the outpatient department ($N = 2$) who were available during the time period of this study. The mean duration of illness, defined as the length of time since the first hospitalization, was 6.8 years ($SD = 7.6$; range = 2–31 years). All patients were receiving standard neuroleptic medications at the time of testing. Patients were excluded if they had histories of epilepsy, head injury with significant loss of consciousness, or other known neurological conditions.

The 25 normal comparison subjects (16 male and nine female) were randomly selected individuals who were approached while they were sitting in the lobby of the university hospital, a general medical facility providing health care for the county from which the patients were drawn. This group consisted of nonpsychiatric outpatients at the hospital ($N = 8$), hospital workers ($N = 5$), and patients' visitors ($N = 12$).

Characteristics of the three groups are shown in table 1.

Within the first 2 weeks after admission, all patients were interviewed with the modified Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (15), and clinical ratings were assigned by a trained psychiatrist using the Scale for the Assessment of Negative Symptoms (16) and the Scale for the Assessment of Positive Symptoms (17). A final diagnosis was made by one of the authors (L.E.D.), who used information from the interviews, medical records, clinicians' observations, and family members. The normal comparison subjects were screened with the SADS-L and the Structured Interview for DSM-III Personality Disorders (18) by a trained interviewer. No individual who received a diagnosis of a major psychiatric or personality disorder was included in the normal group.

All of the inpatients were tested approximately 2 weeks after admission, after being stabilized on medication regimens. Outpatients and day hospital patients ($N = 9$) were tested during the course of their treatment, but not necessarily within 2 weeks of admission to their program. All subjects received a neuropsychological test battery, which included the following tests (19).

1. The measures of language function were the Pro-rated Verbal IQ, the standard score on the Reading subtest of the Wide Range Achievement Test, the Boston Naming Test, the Controlled Oral Word Association Test, and the Word Attack subtest of the Woodcock Reading Mastery Test.

2. The measures of executive/frontal function were the Wisconsin Card Sorting Test, the Booklet Categories Test (abbreviated form, subtests I–IV and VI), and the Stroop Color-Word Test. The Wisconsin Card Sorting Test is thought to be sensitive to dysfunction in the dorsolateral prefrontal cortex (10).

3. The measures of verbal memory included the Logical Memory and Associate Learning subtests of the Wechsler Memory Scale and the California Verbal Learning Test. Verbal memory has been associated with left temporal lobe function (20).

4. The measures of spatial memory were the Visual Reproduction section of the Wechsler Memory Scale and the Benton Visual Retention Test. Visual/spatial memory has been associated with right temporal cortical function (20).

5. The tests thought to reflect global cortical function, as well as overall concentration and motor speed, were the Trail Making Test (parts A and B), the Symbol Digit Modalities Test, the Cancellation Test, and the Finger Tapping Test.

6. Measures of finger agnosia and graphesthesia were given to assess sensory/perceptual function.

7. The Ravens Coloured Progressive Matrices (Ravens IQ) was administered to measure visual/perceptual capacity.

Scores on the Scale for the Assessment of Negative Symptoms and the Scale for the Assessment of Positive

^aSignificant difference between B and C ($p < 0.05$, post hoc Tukey test).

^bSignificant difference between A and C ($p < 0.05$, post hoc Tukey test) and significant difference between B and C ($p < 0.05$, post hoc Tukey test).

Symptoms were composite scores, or the sums of all individual items in each category.

Because of the large number of variables generated, summary scales for each function—language, executive, verbal memory, spatial memory, concentration/speed, and sensory/perceptual—were constructed, as well as a global scale, which was the average of the other scale scores. A left hemisphere and a right hemisphere scale were also constructed from the tests purported to reflect lateralized function. For the left hemisphere scale, language function, verbal memory, and right-handed sensory/perceptual and motor test scores were summed and averaged. For the right hemisphere scale, the Ravens IQ score, measures of visual/spatial memory, and left-handed test scores were similarly combined. Standardized z scores based on the mean scores and standard deviations of the normal comparison group were summed and averaged for each function. Internal reliability for the first six scales was good, with coefficient alphas ranging from 0.67 to 0.87. (An expanded explanation of the construction of the scales may be obtained from the first author on request.)

To evaluate the possibility that the acuteness of the psychosis might obscure differences between groups, 16 inpatients (eight schizophreniform, three chronic schizophrenic, three subchronic schizophrenic, and two with paranoid personality disorders) were retested on alternative versions (where available) of the Prorated Verbal IQ, the Wechsler Memory Scale, the California Verbal Learning Test, the Trail Making Test, the Controlled Oral Word Association Test, and the Wisconsin Card Sorting Test 1 week before hospital discharge (on average, 6–8 weeks after they were first tested). All patients demonstrated a substantial reduction in psychotic symptoms as measured by the Scale for the Assessment of Positive Symptoms.

In the statistical evaluation, because the groups differed significantly in age and level of education, a multivariate analysis of covariance (MANCOVA) with age and years of education as covariates was applied to the

scores on the first six summary scales to test for a main effect of group (first-episode patients, patients with chronic schizophrenia, normal subjects). A second MANCOVA was performed on the left hemisphere and right hemisphere scale scores. Scores on the individual neuropsychological tests contributing to the summary scales for which there was an overall effect were subjected to analyses of covariance (ANCOVA) controlled for age and level of education. Post hoc tests were based on Tukey's honestly significant difference for unequal samples (Spjotvoll and Stoline test [21]). These were based on residualized mean square error within cells, adjusted for the covariates. Pearson product-moment correlations were used to test associations between the neuropsychological summary scale scores and scores on the Scale for the Assessment of Negative Symptoms, scores on the Scale for the Assessment of Positive Symptoms, and the duration of illness. Paired t tests were computed for the individual tests of the subgroup of 16 patients, comparing their performances within 2 weeks of admission and within 1 week of discharge. A repeated measures two-group ANCOVA (Group by Hemisphere) was computed to compare the left and right hemisphere scale scores of the two patient groups.

RESULTS

There were statistically significant differences between the three groups, after adjusting for age and education, in scores on the first six summary scales (overall multivariate $F = 2.75$, $df = 12, 146$, $p < 0.002$). The MANCOVA for the left and right hemisphere scale scores was also significant ($F = 6.25$, $df = 4, 154$, $p < 0.0001$). Results on the summary scales are listed in table 2, and results on the individual tests are listed in table 3.

Both the schizophreniform and the chronic patients performed significantly worse than the normal subjects on all of the scales except the language scale, on which only the chronic patients performed worse than the

normal subjects, and the sensory/perceptual scale, on which both patient groups performed the same as the normal subjects. Post hoc tests revealed no significant differences between schizophreniform and chronic patients on any neuropsychological summary measure. The repeated measures ANCOVA yielded a main effect for hemisphere ($F=24.5$, $df=1$, 54 , $p < 0.000008$), indicating that left hemisphere function was significantly more impaired than right hemisphere function in both the schizophreniform and the chronic groups. The effect for group and the Group by Hemisphere interaction were not significant in this analysis.

Within the chronic schizophrenic group, separate analyses revealed no differences between patients with the paranoid and nonparanoid (disorganized, undiffer-

entiated) types on any neuropsychological measures. In addition, the MANCOVA and ANCOVAs were recomputed without the data on the four schizoaffective patients in the chronic group. Results identical to those of the original analyses were obtained. Paired t tests (two-tailed) on the 21 test variables indicated that at the second testing, patients performed the same as at the first testing, except for the number of correctly obtained categories on the Wisconsin Card Sorting Test, which was lower ($t=2.1$, $df=15$, $p < 0.05$). Pearson correlations between the neuropsychological summary scale scores and scores on the Scale for the Assessment of Negative Symptoms, scores on the Scale for the Assessment of Positive Symptoms, and the duration of illness yielded no significant associations.

DISCUSSION

Both the schizophreniform and the chronic schizophrenic patients had lower scores on measures of executive function, verbal and spatial memory, concentration/speed, and left and right hemisphere function than the normal comparison subjects. Both patient groups also demonstrated relatively greater left than right hemisphere impairment. These findings indicate that first-episode psychotic patients with the *DSM-III-R* diagnosis of schizophreniform disorder have considerable cognitive dysfunction, comparable to that of chronic patients.

In addition, there was no significant association between length of illness and neuropsychological impairment. Our findings were consistent with other studies of chronic patients showing evidence of global cognitive dysfunction suggestive of both left and right hemisphere involvement (8, 22), but also with other studies which suggest that the left hemisphere may be preferentially affected in schizophrenia (4-7). It should be noted that executive/frontal functions were not significantly more impaired than most other cognitive functions in the patient groups, arguing against the notion of selectivity of frontal lobe involvement in schizophrenia. The patients also demonstrated evidence of verbal and spatial memory deficits, consistent with recent reports of impairment on tasks of temporohippocampal functions (11). Patients appeared to have good sensory/perceptual function.

One possible explanation for the lack of differences between the schizophreniform and chronic schizophrenic groups could have been the effect of acute psychotic state on test results. However, this appeared unlikely, since retest data on the group of 16 patients who were in remission and close to discharge indicated few differences in cognition from that seen at admission. Thus, it appears that the deficits in both groups of patients were not state-related phenomena. In general, there is also little evidence that severity of illness affects neuropsychological test scores (23-25).

Another factor that could have affected the interpretation of the neuropsychological test scores of the schizophrenic patients was medication. In this study, first-episode and chronic patients were taking comparable doses of medication, the only difference being that the chronic patients had been taking medication for approximately 7 years. In general, medication typically improves cognitive performance, particularly on measures of attention and information processing (26). In a recent study by our group (27), patients taking medication performed as well as those not taking medication on almost all neuropsychological measures, with the exception of tests of motor speed.

Our results are consistent with those of longitudinal studies in which cognition was measured before the onset of illness, i.e., during military induction and several years later (12, 13, 28). In general, these studies indicated a decrement in most subtest scores after the onset of illness, thus providing evidence for a fairly rapid decline in cognition associated with the onset of illness.

There is some debate about whether brain morphological changes predate the onset of schizophrenic illness. Ventricular enlargement has been reported in patients close to the onset of illness (29, 30), in patients ill for less than 2 years (31, 32), and in one patient who had not yet developed the illness (33). A number of studies have demonstrated the association of structural abnormalities with neuropsychological deficits (34). Previous studies by our group have shown that some change in brain morphology is evident in the first episode of illness (30). The fact that structural changes have been shown to appear early in illness may explain the degree of cognitive deficit seen in first-episode patients.

Long-Term Study of the Sleep of Insomnia Patients With Sleep State Misperception and Other Insomnia Patients

Rafael J. Salin-Pascual, M.D., DM.Sc., Timothy A. Roehrs, Ph.D.,
Lori A. Merlotti, M.S., Frank Zorick, M.D., and Thomas Roth, Ph.D.

Objective: The objectives were 1) to investigate differences among patients with subjective insomnia (sleep state misperception), patients with objective findings of insomnia, and normal volunteers and 2) to assess the consistency of the sleep findings during a 2-month period. **Method:** Twenty-one subjects were studied. Subjects with sleep state misperception (N=7) had insomnia complaints for more than 1 year, no objective sleep disturbance, and sleep efficiency of 90% or greater (on the diagnostic screening sleep recording), while subjectively estimating that sleep time was less than 6.5 hours. Subjects with objective insomnia (N=7) met the same subjective criteria, but objectively sleep efficiency was 85% or less. Normal subjects (N=7) had no insomnia complaints and objective sleep efficiency of 90% or greater. All subjects were recorded on 2 consecutive nights three times with a 3-week period between each pair of nights (6 standard all-night polysomnographic sessions of 8 hours). A subjective sleep questionnaire was administered after each sleep recording night. **Results:** Sleep stage variables (percentages) were similar between the two insomnia groups, and both were different from the normal subjects. Sleep continuity variables were disturbed in the objective insomnia group, but they were similar in the sleep state misperception and normal groups. Both insomnia groups rated their sleep as inadequate on the questionnaires and differed from the normal subjects. The distinct sleep patterns of each of the three groups did not vary over the 6 nights of assessment. **Conclusions:** Sleep state misperception may be a prodromic or transitional state of sleep dysfunction between normal sleep and the sleep pattern of objective insomnia.
(Am J Psychiatry 1992; 149:904-908)

Insomnia with no objective findings in the first (1979) Diagnostic Classification of Sleep and Arousal Disorders (1), or sleep state misperception in the 1990 International Classification of Sleep Disorders (2), is a disorder in which there is a complaint of insomnia but no polysomnographic evidence of a sleep disturbance. Objective sleep disturbances have been reported in all other insomnia diagnostic categories. These sleep disturbances have typically included a longer sleep latency and shorter sleep continuity (3). In addition, sleep stage alterations have been reported in objective insomnia but not in sleep state misperception. The amount of slow-wave sleep is less and the amount of stage 1 is greater in objective insomnia patients than in age- and sex-matched control subjects

(4, 5). The amount of REM sleep has not been found to be different.

Previous studies (6, 7) reporting that the sleep of patients with sleep state misperception does not differ from that of normal subjects typically used 1 to 3 nights of polysomnographic recording. However, it has been reported that patients with insomnia have high night-to-night variability in the quality of their sleep (8). This variability is particularly apparent during placebo conditions in longitudinal psychopharmacological studies of such patients (9). Previous studies have shown that insomnia patients have disturbed sleep on approximately 50% of the nights. Hence, on the basis of probability theory, a 5-night sample would be required for identifying, with greater than 95% confidence, sleep disturbance in patients with sleep state misperception insomnia. Thus, it has been argued that sleep state misperception is a pseudodiagnostic category (10) in that the diagnosis is typically made on the basis of an inadequate sample of sleep (i.e., 1 to 3 nights).

Another issue in evaluating the validity of sleep state misperception was raised in a recent review (11). The review questioned the need for a subclassification of the

DSM-III-R diagnosis of primary insomnia under which the sleep state misperception diagnosis of the International Classification of Sleep Disorders would fall. It was argued that sleep state misperception is a characteristic of all chronic insomnias and that such patients are merely at one extreme of a continuum. However, the review clearly indicated that factors which determine how sleep is subjectively assessed are not known. Given an adequate sample of the sleep of patients who misperceive their sleep, information regarding the presence or absence of consistent sleep stage differences in such patients compared to other insomnia patients and normal subjects will provide a basis for further evaluating the validity of sleep state misperception.

The first objective of the present study was to evaluate the consistency of sleep in sleep state misperception insomnia. This was done during a 2-month period with 2-night samples every 4 weeks. Given a larger sample of the sleep of patients with sleep state misperception, a second objective was to compare the polysomnographic characteristics of such patients to those of patients with insomnia with objective findings and age-matched normal subjects. These data were collected as the baseline nights before each of three conditions in a larger study of the self-administration of benzodiazepine hypnotics.

METHOD

Subjects

Twenty-one men and women (seven subjects per group) 30–50 years of age were studied. All were in good health (except for a complaint of insomnia) as determined by the screening procedure. All the subjects were recruited through a newspaper advertisement stating: "Wanted: healthy men & women, with or without difficulty sleeping, 18–55 years of age, for participation in sleep studies." All subjects gave written informed consent and received payment for their participation.

Procedure

Subjects underwent a medical history, a physical examination, and laboratory blood and urine tests before a screening nocturnal polysomnogram. Subjects were excluded if they had acute or chronic medical conditions that required treatment or were currently taking CNS-active drugs. Urine drug screening was used to verify subjects' reports. Anyone with a history of psychiatric disorders, drug addiction, or alcoholism was excluded. Finally, anyone who had taken a benzodiazepine hypnotic within the past year was also excluded.

Each subject underwent a sleep disorders evaluation including a sleep history and a nocturnal polysomnogram. Evaluations also included a psychometric battery consisting of the MMPI and the Profile of Mood States (POMS). Subjects recruited as normal subjects reported no history of insomnia, estimated their nightly

sleep time as greater than 7 hours, and had a sleep efficiency on the screening nocturnal polysomnogram of 90% or greater. There were four women and three men in this group; the mean age was 35.6 years ($SD=5.9$). Subjects qualifying as patients with sleep state misperception insomnia had more than a 1-year history of insomnia, estimated their nightly sleep time as less than 6.5 hours, had a sleep efficiency of 90% or more on the diagnostic polysomnogram, and underestimated their sleep time for the diagnostic night by at least 1 hour. There were three women and four men in this group; the mean age was 36.4 years ($SD=5.9$). Insomnia subjects with objective findings were included in the study if they had more than a 1-year history of insomnia, estimated their nightly sleep time as less than 6.5 hours, and had a sleep efficiency of 85% or less. There were four women and three men in this group; the mean age was 35.4 years ($SD=6.3$). All subjects had no evidence of apnea or periodic leg movements on the nocturnal polysomnogram.

Those subjects who passed the diagnostic screening were entered into the study within 1 week of having qualified. On study nights subjects arrived at the sleep laboratory 1.5 hours before their usual bedtime, which was held constant throughout the study. They were prepared for standard polysomnographic assessment. A standard all-night polysomnogram was obtained on each of the 6 nights. A set of 2 nights was recorded three times, with an interval of 4 weeks between samples.

The polysomnogram included the central and occipital EEG, electro-oculogram, and submental electromyogram (EMG) collected from standard placements and monitored continuously for 8 hours. The diagnostic screening also included nasal and oral respiration measured with thermistors and bilateral leg (anterior tibialis) EMG. Subjects were awakened after 8 hours in bed. After arising each morning they completed a sleep questionnaire regarding the quantity and quality of the previous night of sleep.

The following study restrictions were adhered to by all participants: 1) no alcoholic or caffeinated beverages after 4:00 p.m. on study nights, 2) no napping during the study, 3) no changes in bedtimes or wake times during the study, 4) 8 hours in bed each night during the study, and 5) no medication without approval of the investigator.

Each polysomnographic recording was scored manually in 30-second epochs according to the standards of Rechtschaffen and Kales (12). Records were coded so that scorers were unaware of the participants' group. Variables reflecting sleep continuity included total sleep time, defined as number of nonwake epochs from the beginning of the recording to the end divided by two; wake time during sleep, the number of wake epochs (divided by two) after the onset of persistent sleep (10 minutes of continuous sleep) before final awakening; latency to persistent sleep, the number of epochs from beginning of recording to the start of the first 20 epochs of nonwake divided by two (i.e., 10 minutes of continuous sleep); and number of awakenings, the number of

entries to wake from persistent sleep that were of at least two consecutive epochs' duration. Variables reflecting sleep architecture included percentage of time in each sleep stage, which was obtained by dividing minutes of the stage by total sleep time multiplied by 100; and the latency to REM sleep, the number of non-wake epochs from beginning of recording to the first epoch of stage REM divided by two.

Mixed-design analyses of variance (SAS) (13) were conducted on the various polysomnographic measures, with group as the between-subjects factor and night as the within-subjects factor. Conservative probability levels, corrected by the Greenhouse-Geisser procedure, were used for all within-subjects comparisons.

RESULTS

Variables reflecting the efficiency of sleep are shown in table 1. Total sleep time was similar in the normal and sleep state misperception groups, while the objective insomnia group differed from the other two groups. There also was a group effect in the latency to persistent sleep, wake during sleep, and number of awakenings. The objective insomnia group was the main source of statistical differences compared to the two other groups. The normal and sleep state misperception groups were similar, which is consistent with the diagnostic screening night. With regard to the first objective of the study, there was no night effect or

Group by Night interaction, which suggests relatively consistent findings over the 6 nights.

Table 2 displays the subjective assessment of sleep obtained on the questionnaires on the 6 nights for each group. Differences between the groups were found on each variable. The two groups with insomnia complaints were similar and differed from the age- and sex-matched normal subjects in estimated total sleep time, wake during sleep, and latency to sleep. Again, relative to objective 1 of the study, there was no night effect or Group by Night interaction.

Sleep architecture is shown in table 3. A 6-night average of each group is presented. Percentage of stage 1 was similar in the two insomnia groups, and they were higher than the normal group. Percentage of stage 2 was different among the three groups. Delta sleep percentage (sleep stages 3-4) was lower in both insomnia groups and was lowest in the objective insomnia group. Percentage of REM sleep was not different between the objective and sleep stage misperception groups, but both groups had less REM sleep than the normal group. REM sleep latency did not differ among the three groups.

The MMPI profiles of the three groups are illustrated in figure 1. The objective insomnia subjects showed the typical MMPI pattern previously reported for such patients, significantly higher scores on the hypochondriasis (Hs) and depression (D) scales than the normal sub-

FIGURE 1. MMPI T Scores of Patients With Sleep State Misperception (Subjective) Insomnia (N=7) and Objective Insomnia (N=7) and Normal Subjects (N=7)^a

^aThe objective insomnia patients had significantly higher scores on the hypochondriasis and depression scales than the normal subjects (F=3.48, df=2, 18, p<0.03; F=4.59, df=2, 18, p<0.02). The subjective insomnia patients had significantly higher hysteria scale scores than the normal subjects (F=8.43, df=2, 18, p<0.01).

jects. The subjective insomnia subjects were similar to the objective insomnia subjects and also had significantly higher hysteria (Hy) scale scores than the normal subjects. As illustrated, the T scores of both insomnia groups, while different from those of the normal subjects, were not pathologically elevated (i.e., T score more than 70). No group differences in POMS scores were observed.

DISCUSSION

The results of this study showed that the sleep of patients with sleep state misperception was relatively consistent over a 2-month period comparable to normal subjects and other insomnia patients. None of the analyses showed a night effect or an interaction of nights with groups. That is, patients with sleep state misperception consistently showed sleep efficiencies similar to those of the healthy normal subjects, while subjectively experiencing disturbed sleep like that of the other insomnia patients.

The second goal of the study was to determine if group differences in sleep might be detected when a larger sample of sleep was obtained. The major finding with respect to this question was that sleep stage variables were similar in the two insomnia groups but different from the normal group, while variables reflecting

sleep induction and continuity were disrupted only in the objective insomnia group and were similar in the normal and sleep state misperception groups. That is, the larger sample of sleep did reveal differences in sleep staging between sleep state misperception patients and healthy normal subjects.

One important interpretive caution in this study is that the insomnia patients were recruited through the newspaper. Stepanski et al. (14) found no differences in sleep measures between a group of insomnia patients referred by their physicians and a second group of self-referred insomnia patients recruited through the newspaper. However, significant differences were found on psychometric measures and measures of daytime alertness. For this reason, the way in which the patients in the present study were recruited may be a limitation of the study.

Given that precaution, the higher percentages of stages 1 and 2 sleep and lower percentage of stages 3–4 sleep in the sleep state misperception group may explain the disparity between the objective (i.e., polysomnographic) and subjective (i.e., questionnaire) evaluation of sleep. The sleep state misperception group rated their sleep as inadequate on the postsleep questionnaires. It is possible that the lesser amount of deep sleep (i.e., stages 3–4) and greater amount of light sleep (i.e., stage 1) account for sleep misperception in this group. The objective insomnia group also had a misperception of the amount of sleep, albeit less than that of the sleep misperception group.

These data are consistent with the suggestion of Reynolds et al. (11) that sleep state misperception is a characteristic of all insomnia patients. However, these data do suggest that there is a group of patients who complain of poor sleep but have "normal" sleep induction and sleep continuity. Although misperception of sleep is a characteristic of all patients with insomnia, this group represents the extreme of the continuum.

The polysomnographic findings of normal sleep continuity, but sleep stage differences, suggests that sleep state misperception may be a transitional state between normal sleep and a more extreme insomnia condition. In this view, in some insomnia patients, or in the early stages of all insomnia, sleep homeostatic processes produce a redistribution of sleep stages (i.e., more time spent in stages 1 and 2 and less in stages 3–4). In the latter stages of insomnia or in more severe insomnia, sleep homeostatic processes fail and frank wakefulness is observed. Thus, sleep state misperception might be considered the prodromic stage of a future psychophysiological insomnia.

On the other hand, one could argue that sleep state misperception is a distinct subclassification of primary

insomnia. The difference between patients with sleep state misperception and other insomnia patients in MMPI profile, particularly on the hysteria scale, supports such a view. This might suggest that there is a vulnerable personality characteristic that predisposes an individual to development of sleep state misperception.

Finally, whether the subclassification of sleep state misperception has validity and clinical utility hinges on whether it has a distinct etiology, course, and treatment response. At this time there is insufficient information to reach any conclusions. More prospective studies of these patients over time and assessment of their treatment response are needed before any conclusions can be reached.

Conservatorship for Gravely Disabled Psychiatric Patients: A Four-Year Follow-Up Study

H. Richard Lamb, M.D., and Linda E. Weinberger, Ph.D.

Objective: The authors examined the conservatorship process in California by studying a group of psychiatric patients for whom conservatorship was sought; their goal was to determine its effectiveness both during and after the period of conservatorship. **Method:** The subjects were 60 county psychiatric hospital inpatients 18–60 years old for whom temporary (30-day) conservatorships were obtained and who were followed for 4 years. The patients' courses over the 4 years were assessed in terms of whether 1-year conservatorships were obtained, stability (number and length of psychiatric hospitalizations, arrests, serious physical violence, and homelessness), and presence or absence of family support. **Results:** The patients proved to be a severely mentally ill and disabled group. Thirty-five (58%) were granted a 1-year conservatorship sometime during the 4-year study period, and 25 (42%) were not. Both family support and conservatorship appeared to be related to the patients' stability. When one or both were present, there was a significantly greater likelihood of stability. **Conclusions:** The authors believe that for a considerable number of chronically and severely mentally ill individuals, conservatorship would play an important role in their clinical management and treatment by helping to eliminate their chaotic life styles, their cycle of admission and discharge from hospitals and jails, and/or their living on the streets, particularly when family support is absent.

(Am J Psychiatry 1992; 149:909–913)

The provisions for conservatorship of mentally ill individuals in California's Lanterman-Petris-Short Act of 1968 were intended to "allow another individual or agency to act on the person's behalf and to protect his interests when he is unable to care for himself. The conservator may determine what arrangements are necessary to provide the conservatee with food, clothing, shelter, and further treatment, and he may take any appropriate steps necessary to safeguard the person's property" (1, p. 23).

Conservatorship has been supported by many as enabling individuals who would otherwise be long-term residents of psychiatric hospitals to live in the community and achieve a considerable measure of autonomy in their lives (2–4). The argument has been made that by giving up some of their liberty, many conservatees, who would otherwise need to be hospitalized for long periods of time, are able to retain most of their independence and their community status.

Conservatorship based on grave disability has been criticized by a few as having essentially retained long-term commitment and as having imposed involuntary

treatment for the nondangerous mentally ill, conditions they hoped would be eliminated by the new involuntary commitment laws (5–7). These critics, however, do not oppose involuntary treatment for the dangerous mentally ill. They voice concern that conservatorship is a way of maintaining a need for treatment standard and achieving social control over individuals who do not meet the strict criterion of danger to self or others.

The purpose of this article was to study the conservatorship process for individuals 18–60 years old, to describe a group of patients for whom conservatorship was sought, and to ascertain its effectiveness both during and after the period of conservatorship. Does conservatorship enhance community tenure? Does it promote stability of the patient's mental condition and life situation? To what extent does family support and involvement affect and interact with the conservatorship process?

THE CONSERVATORSHIP PROCESS IN CALIFORNIA

Conservatorship proceedings are sought for individuals considered gravely disabled, which, in California, means "a condition in which a person, as a result of a mental disorder, or impairment by chronic alcoholism, is unable to provide for his or her basic personal needs for food, clothing or shelter" (8). Many have accepted the case law interpretation (9–11) that a person is not

"gravely disabled" if he or she is capable of surviving safely in freedom with the help of willing and responsible family members, friends, or third parties. However, if an individual is gravely disabled and is unwilling or unable to accept treatment voluntarily, a conservatorship may be recommended. Most of these recommendations are made after a relatively short period of involuntary hospitalization (i.e., 17 days); however, there are conditions under which a person may be recommended for conservatorship who has not been in an inpatient facility.

Recommendations for conservatorship may be made only by professionals in charge of agencies providing comprehensive evaluation and/or intensive treatment. Generally, the proceedings begin with a period of temporary conservatorship that usually does not exceed 30 days. At this time, the court schedules a conservatorship hearing to follow the expiration of the temporary conservatorship period and appoints a temporary conservator from the public guardian's office or a similar agency. The temporary conservator's role is to determine and arrange for the patient's food, shelter, and care while awaiting the conservatorship hearing. During this period, an evaluation and investigation are also conducted to determine if alternatives to conservatorship are available and to assess the needs of the patient. Irrespective of whether a conservatorship is recommended after the temporary conservatorship has been obtained, the case is reviewed by the court. Moreover, if a conservatorship is recommended, the patient has a right to a court or jury trial.

If the court or jury accepts the recommendation, the patient is placed under a conservatorship for 1 year, which can be renewed at the end of the 1-year period. The conservatorship can also be terminated before the 1-year period is over. Conservatees are entitled to judicial reviews of their status every 6 months.

The court appoints a conservator who is either a private individual or a public agency, e.g., the public guardian's office. The conservator may be granted a number of powers over the conservatee, including those of estate. However, the most commonly granted powers are those related to the conservatee's residential placement, involvement in psychiatric treatment, and management of the conservatee's money. That is, the conservator has the power to place the conservatee anywhere (e.g., at home, in a board and care facility, in a locked skilled nursing facility, or in a psychiatric hospital) and to require that the conservatee attend psychiatric treatment and take medications to remedy or prevent "the recurrence of the conservatee's being gravely disabled" (12).

METHOD

The study subjects consisted of all individuals 18–60 years old in the Los Angeles County/University of Southern California (USC) Psychiatric Hospital for whom temporary (30-day) conservatorships were obtained from January 1, 1986, through March 15, 1986.

This time period was chosen to allow for a 4-year follow-up period in 1990. During the 1986 time period, temporary conservatorships were obtained for 71 individuals. In five cases, both the patient and the family spoke only Spanish and therefore were not included in the study. Three patients were transients who were returned to their home states before the conservatorship proceedings could be concluded; these were also dropped from the study. Of the remaining 63 patients, there was insufficient information for three patients to provide an adequate 4-year follow-up. Thus, the 4-year follow-up group numbered 60.

This study was conducted under the auspices of both the Los Angeles County Superior Court (all conservatorship hearings in the county are held in this court) and the Los Angeles County/USC Psychiatric Hospital, the largest hospital in the county. Both court and hospital records were reviewed, as well as records in the Los Angeles County Department of Mental Health Computerized Management Information System. In some cases, the patient's course over the 4 years and status at 4-year follow-up could be obtained entirely from court and psychiatric records. For the remaining cases, we obtained this information from family and/or friends, staff of board and care homes and other residential facilities in which the patient had been placed, and mental health professionals involved with the patient.

Instability during the 4-year follow-up period was defined as placement in the community marked by 1) a total of 6 months or more of psychiatric hospitalization or 2) a total of 3 months or more of psychiatric hospitalization plus one or more of the following: serious physical violence against others, arrests involving time in jail, and homelessness. Family support was defined as strong, consistent involvement and willingness to provide assistance in the form of living arrangements, emotional support, structure, management of finances, and monitoring of medications, nutrition, and health.

RESULTS

The 60 patients ranged in age from 18 to 60 years (median=35 years). Twenty-nine (48%) were men and 31 (52%) were women. Their educational levels ranged from the fifth grade to 1 year of graduate school (median=4 years of high school). Other characteristics of the 4-year follow-up group are given in table 1.

All 60 patients were placed on a temporary conservatorship during the index admission. Of these, 35 (58%) were granted a 1-year conservatorship sometime during the 4-year study period and 25 (42%) were never granted a 1-year conservatorship during the 4-year period. These two groups did not differ significantly on any of the demographic data given in table 1.

Family Support and Stability

The 60 patients were not randomly placed in the conservatorship and nonconservatorship groups. Rather,

^aTypes of hospitalizations add up to more than 57 because all previous hospitalizations were counted.

they fell into these two groups for a variety of reasons: clinical judgment on the part of the treatment staff based on the patient's clinical course; past history and available resources after discharge, including alternatives to conservatorship; the judgment of the court on these matters; and the wishes of the patient's family. Nevertheless, comparison of the group of patients placed on conservatorship and the group of patients not placed on conservatorship reveals a striking finding with respect to family support and the patient's stability during the 4-year study period (table 2). For those patients who were placed on conservatorship, there was no significant difference in their stability or instability

TABLE 2. Family Support and Stability During 4-Year Follow-Up of 60 Patients for Whom Temporary (30-Day) Conservatorships Were Obtained

Support Measure	Patients Placed on 1-Year Conservatorship (N=35)		Patients Not Placed on 1-Year Conservatorship (N=25)	
	Stable	Unstable	Stable	Unstable
Family support	12	6	11	3
Absence of family support	8	9	0	11
Total	20	15	11	14

and whether or not they had family support from the time of their conservatorship to the end of the 4-year study period ($\chi^2=1.37$, $df=1$, *n.s.*). However, for those patients who were never placed on conservatorship during the 4-year study period, there was a highly significant relationship between their stability or instability and the presence of family support ($\chi^2=12.41$, $df=1$, $p<0.001$, Yates' correction).

Of the 29 patients who had unstable courses, all had hospitalizations of 3 months or more, 15 (52%) had hospitalizations totaling 6 months or more, 14 (48%) had been arrested, 16 (55%) had been physically violent against persons, and 11 (38%) had been homeless. There were no significant differences in these areas between those placed on conservatorship and those not. All 29 patients had on numerous occasions showed signs of decompensation that were not promptly and consistently addressed.

Conservatorship and Stability

Of the 35 patients who were placed on conservatorship, 29 (83%) remained stable as long as the conservatorship lasted. However, 21 (60%) of the 35 patients had their conservatorship terminated during the 4-year study period. Of these 21 patients, only nine (43%) remained stable after termination. Of the 12 remaining patients who became unstable, eight manifested instability within 6 months of termination of conservatorship.

Of the total group of 35 patients placed on conservatorship, the mean length of time actually on conservatorship was 26.7 months (median=24 months). While actually on conservatorship, the mean total length of time psychiatrically hospitalized was 14.1 months, or 53% of the time on conservatorship (median percentage=50%).

DISCUSSION

This was a 4-year follow-up study of patients in a county psychiatric hospital for whom temporary conservatorships were obtained under California's Lanterman-Petris-Short Act. The typical patient in this study had a schizophrenic or major affective disorder and a

history of multiple psychiatric hospitalizations and outpatient psychiatric treatment. Almost three-fifths were known to have a history of serious substance abuse, half were known to have a history of physical violence against persons, and one-third were known to have previous arrests. Over one-fourth of the patients were living on the streets at the time of the index hospitalization. These findings are not surprising in a group of psychiatric patients classified as gravely disabled.

Follow-up of the study group revealed two subgroups: 35 (58%) patients who were granted a conservatorship sometime during the 4-year study period and 25 (42%) who were never granted a conservatorship. These two groups differed in the relationship between their stability and their family support. For those patients who were never placed on conservatorship, there was a highly significant relationship between the presence of family support and stability. This is in marked contrast to the group who were placed on conservatorship, where there was no significant relationship between family support and stability. These results suggest that the presence of family support may well obviate the need for conservatorship in a number of individuals who would otherwise need it. On the other hand, if the patient improves in the hospital and family support is absent, clinicians should more carefully consider pursuing conservatorship rather than simply dropping the process.

Family Support

Family support in this study often took the form of patients living with families who provided considerable emotional support, monitored the patients' medications and all other aspects of their treatment and rehabilitation, and supervised the patients' money. In other cases, the family convinced the patients that they should live in a supervised setting such as a board and care home but remained involved with the patient by means of frequent visits, working with the board and care home operator on issues of daily living and management of the patient's money. In still other cases, patients lived in a nearby apartment but took their meals with the family and spent considerable time with them.

Looking at the patients who were actually placed on conservatorship, we found further important results. Twenty-nine (83%) of the 35 patients placed on conservatorship remained stable as long as the conservatorship lasted; for the 21 patients whose conservatorship was terminated, only nine (43%) remained stable after termination. Thus, remaining on conservatorship may be a factor contributing to stability. Two-thirds of those who became unstable did so within 6 months of termination of conservatorship.

While the patients were actually on conservatorship they spent an average of approximately half of the time in psychiatric hospitals. For some, conservatorship became a mechanism for long-term involuntary hospitalization. For others, conservatorship permitted intermediate periods of hospitalization in order to achieve

stabilization. For still others, conservatorship appeared to be a key factor in helping to maintain chronically and severely mentally ill individuals in the community.

A case example will illustrate some of the points made here. Minor changes have been made in some of the facts of the case to preserve confidentiality.

Case Example

This 40-year-old divorced woman had her first episode of schizophrenia, paranoid type (*DSM-III-R*), when she was 19 years old, resulting in hospitalization. Over the years she had a number of rehospitalizations. Her marriage of less than a year ended in divorce when she was 28 years old. For 10 years, she lived in numerous board and care homes in her home state. Each time, as she began to feel emotionally close to the board and care staff and residents, she would become increasingly anxious and paranoid and go to live in another board and care home. Finally, she came to California "to better her life." However, for the 2 years before the index hospitalization, she had been living on the streets of Los Angeles. Bizarre behavior brought her to the attention of the police, who transported her to the county psychiatric hospital. In the hospital, she had a stormy course and would agree to no reasonable discharge plans. She had no family support in the area. A conservatorship was obtained, and the public guardian's office was named conservator. After 2 months in the county hospital, the patient was transferred to the state hospital, where she remained for 10 months. The conservatorship was renewed and the patient was discharged to the community. She lived in a board and care home and attended outpatient treatment for several months, when her family in her home state petitioned the court to allow the patient to return to her home state. The patient had not been willing to do this but now she readily agreed. The conservatorship was terminated and the patient went to live with a sister on a temporary basis. After a few months, the patient entered a satellite housing program but maintained a close relationship with her sister, who was extremely supportive. A year later, the sister was transferred to another state, and several weeks after the move the patient, now without her support and involvement, decompensated. At the 4-year follow-up date, the patient was in the state hospital where she had been since her sister's departure. The sister was concerned but expressed helplessness with regard to her ability to help the patient from afar.

Conservatorship enabled this patient to become stabilized during a hospitalization of approximately 1 year. She was then willing, as she had not been before, to accept the support and structure offered by her family. The importance of this is shown by her stability when she had strong family support and her prolonged decompensation immediately after this support was withdrawn. Thus, this patient was stable while on conservatorship or while she had family support but unstable when she had neither.

CONCLUSIONS

The subjects of this study were patients for whom temporary conservatorships were obtained. These patients proved to be severely mentally ill and disabled.

They fell into two groups: those who were granted a conservatorship sometime during the 4-year study period (58%) and those who were not (42%). Both family support and conservatorship appeared to be related to stability. When one or both were present, there was a significantly greater likelihood of stability in terms of absence of problem areas, such as number and length of psychiatric hospitalizations, arrests, physical violence, and homelessness. When both family support and conservatorship were not present, stability was significantly less likely.

Conservatorship based on grave disability frequently embodies a need for treatment standards for nondangerous patients. We believe this is a more humane approach than the alternative of simply doing nothing for patients too ill to accept treatment. In particular, when family support is not available, conservatorship can mean the difference between a life style characterized by chaos and a life that includes the opportunity to be free from the dysphoria resulting from being admitted to and discharged from hospitals and jails and/or on the streets.

For a considerable number of chronically and severely mentally ill individuals, conservatorship would play an important role in their clinical management and treatment. Conservatorship does not necessarily eliminate intermediate or long-term psychiatric hospitalization; in a number of cases it facilitates it. However, in

many cases, by giving up a little of their liberty through the conservatorship process, these individuals are able to avoid long-term hospitalization and thus retain most of their freedom.

Differences in the Effects of Divorce on Major Depression in Men and Women

Martha Livingston Bruce, Ph.D., M.P.H., and Kathleen M. Kim, M.D., M.P.H.

***Objective:** The authors examined the relationship between marital disruption and major depressive episodes. **Method:** The analyses were based on longitudinal, community-based data from the New Haven Epidemiologic Catchment Area (ECA) program on respondents 18–60 years old. The presence and history of major depression was assessed by using the National Institute of Mental Health Diagnostic Interview Schedule. **Results:** Marital disruption was associated with higher prevalence rates of major depression in both men and women, but only men had a greater risk of a first-onset major depression. Differences between men and women in rates of major depression were observed only among married subjects. **Conclusions:** These findings suggest that the relationship between marital disruption and major depressive episode differs for men and women. They also provide further evidence that differences between men and women in rates of depression vary by marital status.*

(Am J Psychiatry 1992; 149:914–917)

In the United States, marriages have a substantial likelihood of ending in divorce (1, 2). Although there is little doubt that marital disruption is associated with considerable emotional turmoil (3), the extent to which marital separation or divorce is a risk factor for a major depressive episode is unclear. Most information on the relationship between marital status and clinical assessments of depression has been drawn from cross-sectional community studies (4, 5) or studies of psychiatric patients (6, 7). In both types of studies, a history of depression before the changes in marital status is not assessed, so that groups at risk for first-onset episodes are determined by potentially biased retrospective reports. The only available longitudinal data in community samples come from studies that assessed depressive symptoms rather than the criteria for major depression. These studies indicate higher rates of depressive symptoms during periods of marital disruption (8, 9); however, these studies did not determine current or past history of major depression.

In assessing the effects of marital disruption, it is important to designate the appropriate reference groups. Researchers generally combine married persons into a

single category, but evidence from community and patient samples indicates that unhappily married adults have higher rates of depression or poorer mental health than their happily married counterparts (10–14). Divorced or separated individuals may well have higher rates of major depressive episodes than happily married individuals but not higher rates than unhappily married individuals. Similarly, the short-term impact of marital disruption has to be distinguished from the longer-term consequences of life as a divorced person.

In this study, we use longitudinal data from the New Haven Epidemiologic Catchment Area (ECA) program to examine several questions about the relationship between marital disruption and risk for major depression: Are individuals undergoing marital disruption at high risk for a major depressive episode? Does marital disruption increase the risk of a first-onset major depressive episode? Are the effects of marital disruption equivalent for men and women?

METHOD

Data for these analyses were collected as part of the New Haven ECA program. The ECA program is a collaborative multistage study of the prevalence and incidence of major psychiatric disorders and the use of health and mental health services in five U.S. sites (15). Our analyses are confined to the New Haven data to take advantage of information on marital quality unique to the New Haven site.

Beginning in July 1980, 5,034 interviews (including an oversample of elderly respondents) were obtained from a multistage probability sample of adults 18 years

Received April 17, 1991; revision received Nov. 6, 1991; accepted Dec. 12, 1991. From the Departments of Epidemiology and Public Health and Psychiatry, Yale University School of Medicine. old and older living in a 13-town region of the greater New Haven area. These interviews represented a response rate for the first stage of 78% ($N=5,034$); 81% ($N=4,081$) of these respondents were reinterviewed after approximately 6 months; 91% ($N=3,694$) of the second-stage respondents were interviewed approximately 6 months later. The methods used in the ECA project have been described in greater detail elsewhere (15, 16).

The objectives of this study focused on a subsample of respondents, namely, 54 respondents who reported that they separated from or divorced their legal spouses over the course of the study period. This group included subjects with three types of change of legal marital status: married subjects who separated from their spouses ($N=14$), married subjects who divorced ($N=11$), and separated subjects who divorced ($N=29$). These three subgroups were combined to increase the size of the index group of interest after initial estimates indicated that their risks of major depressive episodes were similar. To minimize age variation, one 73-year-old subject was omitted from the study, leaving 53 subjects 18–60 years old.

The index group was compared with three other groups of subjects 18–60 years old whose legal marital status did not change during the study period. The first group comprised married respondents who at the first interview reported themselves as "getting along with their spouse" ($N=708$). This group was considered happily married. The second comparison group comprised married respondents who at the first interview reported themselves as "not getting along with their spouse" ($N=259$). This group was considered unhappily married. The third comparison group comprised separated or divorced respondents whose legal status did not change over the study period ($N=205$). The duration of their marital status was not known.

The two comparison groups of married respondents were differentiated by the self-reported quality of their marriages. We used the reports only from the first interview to avoid confounding subsequent reports of marital quality with depressive status.

Diagnostic assessment was based on information gathered by lay interviewers using the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (17, 18). Depressive episodes were assessed by computer algorithms using the *DSM-III* criteria of having a period of 2 weeks or more of dysphoric mood as well as symptoms from at least four of the eight *DSM-III* depression symptom groups. Respondents met criteria for major depression if they reported experiencing at least one depressive episode but no manic symptoms ever. Depressive episodes in response to bereavement were not coded as major depression unless the episode lasted a year or more.

We used unweighted data in subjects classified according to their marital status to compare rates of major depression occurring between the first and last interviews, a period of approximately 1 year. Chi-square tests generated from logistic regression models, adjusted for age, estimated the relative rates between subgroups.

Period prevalence is defined as the proportion of subjects in the total group who reported an episode of major depression between interviews. Incidence is defined as the proportion of the group at risk for first-onset major depression who reported a depressive episode between interviews. Respondents excluded from the group at risk for a first-onset major depression were 1) respondents who, at the first interview, reported either a history of major depression or a history of mania and 2) respondents who, at the subsequent interview, reported an age at onset of major depression that was younger than their age at the first interview. The latter criterion compensates for possible underreporting of past history of depression (19, 20) as well as changes in the DIS version used in the subsequent interview. This approach should minimize overinflating incidence rates because any remaining cases of unreported past history would likely be in the denominator rather than the numerator.

RESULTS

The analyses first compared the sex, age, and history of major depression of subjects in the marital disruption group and subjects in the other three marital categories. The proportion of women in the marital disruption group (29 [54.7%] of 53) was significantly lower than in the groups of separated or divorced respondents whose legal status did not change over the study period (147 [71.7%] of 205) ($\chi^2=5.84$, $df=1$, $p<0.02$) but did not differ from those in the two groups of respondents who remained happily or unhappily married during the study period. The average age (36.9 years) of the subjects in the marital disruption group did not differ from that of any of the other three groups.

Nine (31.0%) of the 29 women in the marital disruption group reported a history of major depression at the first interview, compared with 33 (8.7%) of the 379 happily married women ($\chi^2=12.39$, $df=1$, $p<0.001$) and 23 (16.4%) of the 140 unhappily married women ($\chi^2=3.22$, $df=1$, $p<0.08$). The 24 men in the marital disruption group did not differ significantly from the men in the other groups in reporting a history of major depression. However, only two of the 24 men in the marital disruption group reported a history of depression, so the statistical power to detect such differences is very low.

Over the course of study year, 63 (9.1%) of the 695 women and 26 (4.9%) of the 530 men reported an episode of major depression. The prevalence of major depression for men and women in each marital category is shown in table 1. The prevalence of major depression in the women who experienced marital disruption was 3.1 times higher than it was in the happily married women ($\chi^2=6.83$, $df=1$, $p<0.009$), 2.1 times higher than in the unhappily married women ($\chi^2=2.54$, $df=1$, $p<0.11$), and 1.7 times higher than in the women who had been divorced or separated before the study began ($\chi^2=1.47$, $df=1$, $p<0.23$). For men, the pattern was similar but more extreme; the prevalence of major depression

TABLE 1. One-Year Rates of Major Depression in Married and Unmarried Men and Women

Marital Category	Women			Men			Sex Ratio (Female:Male)
	N	Major Depression		N	Major Depression		
		N	%		N	%	
All subjects							
Happily married	379	25	6.6	329	6	1.8	3.7:1
Unhappily married	140	14	10.0	119	10	8.4	1.2:1
Divorced or separated before study began	147	18	12.2	58	6	10.3	1.2:1
Divorced or separated during study period	29	6	20.7	24	4	16.7	1.2:1
Subjects with no history of depression							
Happily married	344	11	3.2	318	1	0.3	10.7:1
Unhappily married	116	6	5.2	102	1	1.0	5.2:1
Divorced or separated before study began	103	4	3.9	47	2	4.3	0.9:1
Divorced or separated during study period	20	1	5.0	21	3	14.3	0.3:1

among the men in the marital disruption group was 9.3 times higher than it was in the happily married men ($\chi^2=11.74$, $df=1$, $p<0.001$), 2.0 times higher than in the unhappily married men ($\chi^2=1.39$, $df=1$, $p<0.24$), and 1.6 times higher than in the men who had been separated or divorced before the study began ($\chi^2=0.54$, $df=1$, $p<0.46$).

The magnitude of the differences in rates of major depression between the subjects in the marital disruption group and the happily married subjects was similar for men and women. Although the relative effect for men was about 3 times greater, the interaction with sex was not significant ($\chi^2=1.58$, $df=1$). Significant differences between men and women in prevalence rates of depression were observed only for the happily married ($\chi^2=8.39$, $df=1$, $p<0.01$).

Subjects with a past history of major depression or mania are omitted from the estimated incidence rates in the lower half of table 1. Because approximately two-thirds (60 of 89 subjects) of the subjects found to have major depression reported previous histories of depression, the remaining number of first-onset cases was too small to conduct statistical tests of significance. The trends in rates of depression for men and women, however, are worth noting. Among women who were at risk for a first episode of depression, there was little variability in rates of major depression across marital status groups. However, for men, the marital disruption group was substantially more likely to report first-onset depression than the other marital status groups.

In comparison to the happily married group ($\chi^2=4.83$, $df=1$, $p<0.05$) and the unhappily married group ($\chi^2=3.11$, $df=1$, $p<0.10$), the effects of marital disruption on the likelihood of first-onset major depression were greater for men than women. Rates of first-onset major depression were higher in women than men only among the happily and unhappily married groups.

DISCUSSION

To summarize, prevalence rates of major depression were higher among men and women experiencing mari-

tal disruption than among the happily married. Among respondents without a history of depression or mania, marital dissolution was associated with a higher risk of first-onset major depression for men but not for women. Differences between men and women in rates of major depression varied by marital status: the prevalence rates were higher for women only in the happily married group.

Although the process of separation or divorce may have substantial personal, social, and economic consequences for both men and women, this study found that the effects of marital disruption on the risk of first-onset major depression were greater for men than for women. These findings are consistent with previous studies reporting that the psychological advantages of marriage are greater for men than women (4, 21, 22), which suggests that the impact of marital disruption may be more detrimental to men. Other retrospective studies also suggest that women experience depressive episodes earlier in the process of marital disruption than men (23, 24). However, the current findings differ from reports that personal events have comparable impact on men and women (25, 26) or that divorce burdens women disproportionately with financial strains (1).

It is important to note that our study design did not allow the development of a temporal sequence of events, i.e., the timing of the marital disruption in relation to the onset of the major depressive episode. Although the New Haven study included an intervening DIS assessment, the data were too sparse to analyze three points in time. Marital disruption is not a single, acute event; the process generally develops over time, as does major depression. Indeed, much of the literature suggests that problems in marriage "trigger" (14) or are precursors (12) of depressive episodes. The assumption is that the marital disruption and depressive episode are coterminous events.

Several other limitations of this study should be noted. The number of respondents reporting marital disruption was too small to compare the risk of depression by age, for example, or by initial reports of marital happiness (preliminary estimates suggested no difference in effect by initial reports). The study was limited

to adults 18–60 years old because marital disruption is especially rare among the elderly (2, 27). Finally, this study describes the relationship only between marital disruption and major depression; other research indicates that marital disruption may also be related to other psychiatric problems such as anxiety symptoms or substance abuse (28).

There were too few respondents with a past history of depression in this study to compare recurrence rates by marital groups. However, the rate of recurrence for major depressive episodes is estimated at about 50% (*DSM-III-R*, p. 228). Even with the small subsamples, the recurrence rates in our marital disruption groups were not high (one of two men; five of nine women), nor did they seem to differ from the rest of the sample.

It is interesting to compare these findings with studies of the newly bereaved. In another ECA study, the prevalence rates of major depressive episodes were higher among newly widowed men and women than among married men and women (29). However, there was no sex difference in the effects of bereavement on the risk of a first-onset depressive episode. Newly divorced subjects were more likely to have a past personal or familial history of depression than newly widowed subjects (especially newly widowed women) (29, 30). For men, both types of losses were associated with a greater risk of a first-onset depressive episode. According to *DSM-III-R*, depressive symptoms are a normal reaction to the death of a loved one and most depressions of bereavement are not considered major depressive episodes. These exclusion criteria do not apply to marital separation or divorce. Although the etiology of the processes may differ, both marital disruption and conjugal bereavement are characterized by the loss of a spouse. Given the similarity in the nature of the two events and in their risk for depressive reactions, the application of different duration thresholds in the diagnostic criteria may be worthy of reconsideration.

The prevalence of major depression was 3.7 times higher among happily married women than among their male counterparts but comparable for all other marital categories. These patterns were even more extreme for first-onset depression. Since the happily married group was also the most common in our and other study populations, most reported sex ratios for the risk of depressive episodes in adults are weighted toward observations among the happily married. The findings from the New Haven ECA suggest that men and women facing marital dissolution should be considered at equally high risk for major depression and that, among individuals without a history of depression, marital disruption poses a greater risk for men.

Depression in Patients With Acute Traumatic Brain Injury

J. Paul Fedoroff, M.D., Sergio E. Starkstein, M.D., Ph.D.,
Alfred W. Forrester, M.D., Fred H. Geisler, M.D., Ricardo E. Jorge, M.D.,
Stephan V. Arndt, Ph.D., and Robert G. Robinson, M.D.

Objective: This study was undertaken to examine patients with closed head injuries for the presence of depressive disorders. **Method:** A consecutive series of 66 patients with closed head injuries but no significant spinal cord or other organ system injury were examined by means of a semistructured psychiatric interview. The Hamilton Rating Scale for Depression as well as scales measuring impairment in activities of daily living, intellectual functioning, and social functioning were administered. The patients' CT scans were also examined. **Results:** Seventeen patients had major depression and two had minor depression. The presence of left dorsolateral frontal lesions and/or left basal ganglia lesions and, to a lesser extent, parietal-occipital and right hemisphere lesions was associated with an increased probability of developing major depression. Compared to the nondepressed group, the group with major depression had a higher frequency of previous psychiatric disorder and showed evidence of poorer social functioning. **Conclusions:** Major depression occurs in about one-quarter of patients after traumatic brain injury. This is the same frequency as in other major disorders such as stroke. Major depression appears to be provoked by one or more factors that include poor premorbid social functioning and previous psychiatric disorder or injury to certain critical brain locations. (Am J Psychiatry 1992; 149:918-923)

With an annual incidence of 2 million cases, trauma is the most common cause of brain injury in the United States (1). In approximately 500,000 of these cases, the patients require hospitalization, and 80,000 have long-term sequelae of their brain injuries (1).

The observation that brain injury leads to a variety of neuropsychiatric disorders has been reported in the medical literature for many years. Adolf Meyer (2), for example, identified a number of disorders that he referred to as the "traumatic insanities," and he associ-

ated these disorders with specific lesion locations. Our knowledge about the behavioral and emotional effects of frontal lobe injury is largely the result of studying patients with traumatic brain injury. For instance, one of the best-known and earliest examples of behavioral and emotional changes associated with traumatic injury is Phineas Gage (3). His penetrating frontal lobe injury, caused by a railroad spike, led to a variety of emotional and personality changes, including disinhibition, apathy, loss of appropriate social behavior, and lability of mood.

The quantitation of severity of traumatic brain injury by Teasdale and Jennett (4) led to a large number of studies examining the neurobehavioral consequences of mild, moderate, and severe head injuries (5-7). These studies have identified numerous behavioral and emotional consequences of brain injury as well as numerous prognostic factors related to long-term outcome. There have been relatively few studies of mood disorders associated with traumatic brain injury, however, and most of these studies have used rating scales, questionnaires, or relatives' reports rather than structured mental status examinations and well-established diagnostic criteria to determine the existence of depression (8, 9).

For several years, we have been reporting on the incidence (10), phenomenology (11), course (12), and treatment (13) of mood disorders in patients with focal brain injury due to stroke. We have reported that depression occurs more frequently in patients with either

left dorsolateral frontal cortical lesions (14) or left basal ganglia lesions than in patients with lesions in any other location (15). In addition, for both cortical and subcortical lesions, the proximity of the lesion to the frontal pole was significantly correlated with severity of depression (14).

One of the major questions, however, is whether these findings in stroke patients are generalizable to other brain-injured populations or whether there is something unique about the stroke population that contributes to the prevalence of depression. For example, compared to patients with traumatic brain injury, stroke patients tend to be older, to have potentially recurrent cardiovascular illnesses, and, frequently, to be taking multiple medications for various illnesses.

Any of these factors or other variables might influence the expression of depression and its neuropathological correlates. In addition, the nature of the brain injury is different following stroke than following trauma. Traumatic injury is associated with diffuse axonal shear injury, contusions, and both arterial and venous bleeding, while ischemic infarction and intraparenchymal hemorrhage are the neuropathological mechanisms associated with stroke.

We have conducted one previous study comparing the severity of depressive symptoms in patients who had had strokes and patients with closed head injuries (16). We found that although the stroke patients were more severely depressed than the patients with traumatic brain injury, the difference in severity of depressive symptoms was explained in large part by differences in the location of CT-visualized lesions in the left hemisphere. In addition, for both traumatic brain injury and stroke there was a significant correlation between proximity of the largest lesion to the left frontal pole and severity of depression.

In the present study, patients with acute traumatic brain injury but without multiple system injury (e.g., patients without multiple fractures or intra-abdominal lesions) were examined with the use of structured interviews and diagnostic criteria to determine whether similar lesion locations or other clinical variables would be associated with major depression.

METHOD

Sixty-six patients with acute closed head injuries who had been consecutively admitted to a shock trauma center were included in the study. Patients were excluded if they had open head injuries, spinal cord injuries, or significant multiple system injuries such as multiple fractures, rupture of the spleen, or lung collapse. In addition, patients were excluded if they had a decreased level of consciousness or aphasia that interfered with their ability to comprehend questions administered during a verbal interview (i.e., patients had to be able to follow at least a two-stage command).

Questions regarding personal and family history of psychiatric disorder were included in the structured inter-

view. Information about the existence of previous mood disorder as well as alcohol or other substance abuse, in the family history or the personal history, was specifically asked of each patient and relatives who were present at the time of interview. A psychiatric history was considered positive for a disorder if the patient or a relative appeared to meet the *DSM-III* criteria for that disorder. This diagnosis did not depend on the patient's receiving treatment. None of the patients had a depressive disorder at the time of the traumatic brain injury, and none received the head injury as a result of a suicide attempt.

After they gave informed consent, all patients received detailed psychiatric examinations approximately 1 month after injury. Symptoms of depression, mania, and anxiety were elicited with a modified version of the Present State Examination (PSE) (17) administered by a research psychiatrist (A.W.F.). This is a semistructured psychiatric interview that was modified to examine all symptoms used in the *DSM-III* criteria.

Quantitative mood ratings were obtained with the observer-rated Hamilton Rating Scale for Depression (18), a 17-item scale that measures psychological and physiological symptoms of depression. Cognitive function was measured with the Mini-Mental State examination (19), which has been shown to be a reliable and valid means of assessing a limited range of cognitive functions in several medically ill or brain-injured populations (16). Mini-Mental State scores range from 0 to 30, with scores below 24 indicative of clinically significant cognitive impairment.

Impairment in activities of daily living was measured with the Johns Hopkins Functioning Inventory (16). Scores on this scale range from 0 to 27, with higher scores indicating a greater degree of functional impairment. Social functioning was quantitatively assessed with the Social Functioning Exam and the Social Ties Checklist (20). The Social Functioning Exam, which has been shown to be reliable and valid for patients with stroke, assesses patients' satisfaction with their social functioning by means of a structured interview. Scores range from 0.00 (greatest satisfaction) to 1.00 (least satisfaction). The Social Ties Checklist assesses the number of social connections available to the patient. Scores may range from 0 to 10, with higher scores indicating less social support.

All neurological examinations were conducted by a neurosurgeon (F.H.G.) who was blind to the results of the psychiatric examinations. Results of the neurological examinations were recorded by using the standardized neurological examination form of the Traumatic Coma Data Bank (21).

CT scans were obtained as part of the standard clinical evaluation of patients admitted to the emergency medical services system that administers the shock trauma center. Scans were usually done within the first day after trauma and repeated 1–2 weeks later. All scans were done on a GE-1010 scanner with standard 10-mm axial cuts parallel to the canthomeatal line.

The nature of the lesion (e.g., contusion, intraparenchymal bleeding, subarachnoid hemorrhage) was deter-

mined from the CT scan. All scans were read by a neurologist (S.E.S.) who was blind to the results of the psychiatric examination. All lesion locations were determined and transposed onto templates according to the procedure described by Levine and Grek (22). Subjects with specific lesion locations (e.g., left anterior lesions) were defined as patients whose CT scans showed lesions in those locations (e.g., left dorsal lateral frontal cortex and/or left basal ganglia) regardless of whether lesions were also seen in other locations.

Several of the rating scale scores and other variables showed abnormal distributions. For consistency, we used nonparametric procedures throughout our statistical analyses. For instance, when we compared the depressed and nondepressed groups for differences on the demographic variables (e.g., age, sex), we used Mann-Whitney U or chi-square tests. When we analyzed scores on the six psychiatric rating scales, we conducted an overall multivariate test of significance in order to 1) account for the intercorrelations among scores on the rating scales and 2) control the overall probability of obtaining a significant result by chance (alpha error). This was accomplished with a nonparametric analog of discriminant analysis based on ranks (23). The overall test of significance was taken as the test for the full model including all scales.

Logistic regression was used to test for an association between the diagnosis of depression and lesion location. Again, an overall test was used to control for alpha inflation and interrelations among the lesion locations. Following the significant likelihood ratio test for the full model, backward selection was used to reduce the number of lesion locations considered.

RESULTS

Seventeen subjects met the *DSM-III* symptom and duration criteria for major depression, and 47 had no

diagnosis of mood disorder. Two additional patients met the *DSM-III* symptom criteria for dysthymia (we have referred to this as minor depression), but their data were excluded from further analysis because of the small number in this category. The depressed subjects' mean age was 26.8 years ($SD=5.8$), and the mean age of the subjects without mood disorder was 29.5 ($SD=10.7$). The mean number of years of education was 12.4 ($SD=2.0$) for the depressed group and 12.3 ($SD=2.1$) for the rest of the subjects. The time from injury to interview was 36.6 days ($SD=15.8$) for the depressed patients and 32.1 days ($SD=20.7$) for the patients without mood disorder. Other background characteristics of the study population are shown in table 1.

There were no significant differences between the depressed and nondepressed groups in terms of age, sex, race, marital status, education, socioeconomic class, or medication taken at the time of interview. The study group consisted primarily of men in Hollingshead's socioeconomic class IV who were in their late 20s. There were no significant differences between the depressed and nondepressed patients in the frequency of a past family history of psychiatric disorder.

There was a significantly greater frequency of a previous personal history of psychiatric disorder in the group with major depression (table 1). When patients with histories of alcohol or other substance abuse were excluded, this difference was no longer significant. There was no significant difference between groups in the frequency of a personal past history of alcohol and/or other substance abuse.

There were no significant differences between the two groups in the frequency of any neurological findings. Twenty-six patients (seven with major depression and 19 without depression) had some motor impairment, 13 (seven depressed and six nondepressed) had sensory impairment, and 14 (three depressed and 11 nondepressed) had ocular palsies. Only one of the 17 patients with major depression and four of the 47 nondepressed patients were given a diagnosis of Broca's or Wernicke's aphasia. In the remaining patients who presented with language impairment (five depressed and 14 nondepressed), there was mild global aphasia, transcortical sensory or motor aphasia, or severe anomia.

The Glasgow coma scale scores 24 hours after injury were not significantly different between groups (depressed patients, mean=9.2, $SD=3.4$; nondepressed patients, mean=10.0, $SD=3.4$), nor was there a significant difference in the distribution of mild head injury (Glasgow coma score=12–15; 35% of the depressed and 43% of the nondepressed patients), moderate head injury (Glasgow coma score=8–11; 24% of the depressed and 26% of the nondepressed patients), or severe head injury (Glasgow coma score=3–7; 41% of the depressed and 32% of the nondepressed patients).

Multivariate discriminant analysis showed an overall significant difference between the group with major depression and the nondepressed group in psychiatric rating scale scores (Wilks's lambda=0.38, $F=15.4$, $df=6$, 56, $p=0.0001$). Univariate test statistics disclosed sig-

TABLE 2. Scores on Psychiatric Rating Scales of 64 Depressed and Nondepressed Patients With Traumatic Brain Injury

Scale	Score				Analysis	
	Patients With Major Depression (N=17)		Patients Without Depression (N=47)		F (df=1, 61)	p
	Mean	SD	Mean	SD		
Hamilton Rating Scale for Depression	13.8	3.2	6.8	2.6	37.79	0.0001
Present State Examination	19.6	4.2	6.8	3.6	78.70	0.0001
Mini-Mental State	27.5	2.3	26.5	3.1	1.74	0.19
Johns Hopkins Functioning Inventory	2.2	3.3	1.4	1.8	0.31	0.58
Social Ties Checklist	4.2	1.2	3.6	1.5	2.49	0.12
Social Functioning Exam	0.19	0.16	0.11	0.10	4.92	0.03

nificant between-group differences in Hamilton depression scores, PSE scores, and Social Functioning Exam scores (table 2). There were no significant intergroup differences in intellectual impairment as measured by the Mini-Mental State examination, impairment in activities of daily living as measured by the Johns Hopkins Functioning Inventory, or social connectedness as measured by the Social Ties Checklist.

According to the resulting discriminant function, 18 (29%) of 63 patients were classified into the depressed group and 45 (71%) were classified into the nondepressed group (three patients were excluded from the analysis because of missing data). These findings indicate a 100% sensitivity and a 98% specificity.

Of the 47 nondepressed patients, 41 had abnormal findings on CT scans, and of the 17 patients with major depression, 15 had CT scan abnormalities. Of the total of 56 subjects who exhibited abnormal CT scans, 22 had single focal lesions and 23 had multiple or bilateral lesions. In addition, 13 patients had extraparenchymal hemorrhages (epidural, subdural, or subarachnoid bleeding) or CT evidence of brain edema, brain atrophy, or hydrocephalus. Most of the patients (71% of the depressed and 62% of the nondepressed patients) had CT evidence of brain contusions. There were no significant differences in the frequency of various types of injury between the depressed and nondepressed groups.

To analyze the relation between lesion location and the presence of major depression, a logistic regression model was used. The model included the following location variables: left hemisphere, right hemisphere, cortical, subcortical, single, multiple, frontal, orbitofrontal, temporal, temporobasal, left anterior (i.e., left dorsolateral frontal cortex and/or left basal ganglia), and parietal-occipital. There was an overall significant association between lesion location and the development of major depression ($\chi^2=33.64$, $df=12$, $p=0.0008$). A backward selection procedure was used to remove the nonsignificant variables ($p>0.05$). After their removal, the reduced model included the following lesion locations: left hemisphere only, right hemisphere only, cortical, frontal (i.e., right, left, or bilateral frontal excluding orbitofrontal involvement), left anterior, and parietal-occipital ($\chi^2=31.39$, $df=6$, $p=0.0001$).

The parameter estimates and probabilities of each of

TABLE 3. Maximum Likelihood Estimates for Regression Coefficients of Lesion Locations and Depression in 64 Patients With Traumatic Brain Injury

Lesion Location	Parameter Estimate	Standard Error	Analysis	
			Wald χ^2 (df=1)	p
Left hemisphere	-2.84	1.44	4.08	0.04
Right hemisphere	2.40	1.12	4.74	0.03
Cortical	-3.67	1.45	6.28	0.01
Frontal	-3.58	1.38	6.56	0.01
Left anterior	5.90	1.64	12.97	0.0003
Parietal-occipital	3.75	1.44	6.91	0.009

these six individual variables are shown in table 3. The presence of a left anterior lesion was by far the strongest correlate of major depression. To a lesser degree, parietal-occipital and right hemisphere lesions increased the probability of developing major depression. On the other hand, the presence of left hemisphere, cortical, and frontal lesions was associated with a decreased probability of developing major depression. If we compare the predicted and observed events, the model shows a 70% sensitivity and an 83% specificity.

DISCUSSION

This study for the first time examined patients with traumatic brain injury for depressive disorder with the use of a structured psychiatric interview and *DSM-III* diagnostic criteria. We found that 27% of the patients whose data were analyzed met the criteria for major depression. This frequency is within the wide frequency range for depression reported by other investigators who have used cutoff scores on self-rated depression scales (8) and is close to the frequency of major depression found in patients with stroke (10). Perhaps the failure to use structured psychiatric interviews and defined diagnostic criteria is the reason that the reported frequency of depression following traumatic brain injury has varied from 10% to 60% (24).

This study also found that major depression following traumatic brain injury was significantly associated with lesion location. The presence of left anterior lesions (i.e., left dorsolateral frontal and/or left basal gan-

glia lesions) and, to a lesser degree, parietal-occipital and right hemisphere lesions was associated with a higher probability of developing major depression. On the other hand, the presence of left hemisphere lesions, frontal (i.e., right, left, or bilateral frontal excluding orbitofrontal) lesions, and purely cortical lesions diminished the probability of developing a major depressive disorder. A previous personal history of psychiatric disorder (including alcohol and other substance abuse) was more frequent in the group with major depression. This group also showed evidence of poorer premorbid social functioning.

Before further discussion of this study, several methodological limitations should be acknowledged. First, only patients who were alert and cognitively able to be interviewed were included. Second, only patients with relatively minor injury to other body systems were included, so that a more uniformly injured population, without major disability due to non-CNS injury, could be studied. In addition, the patients were primarily young white men from the lower socioeconomic classes who had histories of alcohol or drug abuse. Although this demographic profile is typical of the population reported in epidemiologic studies of traumatic brain injury (1), our findings may not be applicable to all patient populations with traumatic brain injury. Closed head injuries involve trauma to the entire brain, and it would be misleading to assume that the only areas that have been injured are the ones visible on CT scan.

While it is certain that the extent of brain injury was underestimated in this study (we did not have information from magnetic resonance imaging), it is unlikely that there was any systematic underrepresentation among patients who met the criteria for major depression, since the mean scores on the Glasgow coma scale, the Johns Hopkins Functioning Inventory, and the Mini-Mental State examination and the distribution of mild, moderate, and severe head injuries were not significantly different between groups. In addition, we did not examine the patients for neglect, disturbances in prosody, unawareness of deficits, or denial of illness (disturbances that are usually associated with right hemisphere lesions). It is possible that some patients with these disturbances may not have been able to recognize their inner mental state appropriately.

Given these cautions, what are the implications of this study? First, the study supports our previous finding in patients with stroke of an increased frequency of depression among those with left dorsolateral cortical and left basal ganglia lesions (14, 15). This finding is consistent with a previous study of patients with chronic brain injuries in which anterior left hemisphere lesions were found to be associated with the most severe depressive symptoms in both stroke and traumatic brain injury (16). It is interesting that the association between major depression and left anterior lesions was highly significant despite the "protective" effect associated with the presence of both left hemisphere and frontal lesions. This finding suggests that the left dorsolateral frontal cortex and the left basal ganglia are critical structures in the left hemisphere as far as mood is con-

cerned, and they may represent strategic lesion locations for the initiation of major depression. The probability of developing major depression was also associated with the presence of parietal-occipital lesions and with the presence of right hemisphere lesions.

Grafman et al. (25) reported that depressive symptoms were associated with penetrating injuries that involved the right hemisphere (right orbitofrontal lesions). Their subjects, however, were studied years after the penetrating injuries, without the use of structured psychiatric interviews, and are not comparable to the patients in this study. Lishman (26) also reported that several years after penetrating brain injury, depressive symptoms were more common among patients with right hemisphere lesions. We previously examined the correlates of depression following acute-stroke lesions of the right hemisphere (27). Patients who developed major or minor depression during the in-hospital evaluation for acute stroke had a higher frequency of parietal lobe lesions than the nondepressed or unduly cheerful patients. Finset (28) reported the occurrence of depression following right hemisphere parietal lobe damage. In the present study, we also found that purely cortical lesions were associated with a decreased probability of developing major depression. This indicates that subcortical and basal ganglia lesions may have the strongest correlation with major depression.

We have previously suggested (14) that the mechanism of depression following anterior brain injury may involve the interruption of biogenic amine-containing neurons as they pass through the basal ganglia or frontal subcortical white matter. This hypothesis remains consistent with our findings in the present study.

This study also suggests that premorbid vulnerability factors (personal history of psychiatric disorder and poor social functioning) may be operative in the development of major depression among patients with traumatic brain injury. This is consistent with our findings and those of other investigators in stroke and traumatic brain injury (10, 29) and suggests several areas for further investigation.

Although other investigators have not found that severity of depressive symptoms is significantly correlated with duration of loss of consciousness, duration of post-traumatic amnesia, or the presence of skull fracture (9), depression following traumatic brain injury has been associated with degree of neuropsychological impairment (9). We did not find a significant difference in degree of intellectual impairment between our depressed and nondepressed patients. This may be because we examined less severely injured patients (the mean Mini-Mental State examination scores for depressed and nondepressed patients were 27.5 and 26.5, respectively), and there may have been a "ceiling" effect that precluded demonstrating an influence of depression on intellectual function.

The finding of relatively low Hamilton depression scale scores among the patients with major depression is another important issue. Although these total depression scores were not significantly different from those

we found previously among patients who developed major depression following stroke or myocardial infarction (30), we are examining this issue in more detail in another study (i.e., examining which symptoms are specific to depression following traumatic brain injury). Several facts, however, should be kept in mind. First, the diagnosis of depression was based on meeting the *DSM-III* criteria for depression and was made by research psychiatrists using a semistructured interview. This remains the "gold standard" for depression, and all of the patients met these criteria. Second, the patients were identified on the basis of the existence of traumatic brain injury and not depression and therefore might not have had symptoms as severe as those found in patients at psychiatric institutions. Moreover, the patients with traumatic brain injury who had major depression had Hamilton depression scores that were highly significantly different from those of the nondepressed patients. Third, depressive symptoms included in the Hamilton scale but not used by *DSM-III* for diagnosis may be somewhat different in functional depression and traumatic brain injury depression, and subgroups of patients with traumatic brain injury may be identified on the basis of the presence of different symptom profiles or longitudinal course.

There are probably multiple etiologies for depression after traumatic brain injury. Some may involve single etiologic agents (e.g., genetic factors), while others may involve a complex interaction between organic and psychosocial factors. Moreover, even within the group with lesions in certain critical brain regions, the phenomenology and the pathophysiological mechanisms of depression may be different (e.g., following left anterior as compared with right parietal lesions).

Future studies will need to examine a variety of outcome variables, including the course of these depressions, the dynamic changes in their clinical correlates, their effect on recovery from traumatic brain injury, their etiology, and their response to treatment. These kinds of investigations may ultimately facilitate the early recognition and treatment or prevention of these severe mental disorders.

Regional Cerebral Blood Flow in Childhood Autism: A SPECT Study

Monica Zilbovicius, M.D., Bernard Garreau, M.D., Nathalie Tzourio, M.D., Bernard Mazoyer, M.D., Ph.D., Bernadette Bruck, Jean-Luc Martinot, M.D., Claude Raynaud, M.D., Yves Samson, M.D., André Syrota, M.D., Ph.D., and Gilbert Lelord, M.D., Ph.D.

Objective: The authors investigated a possible cortical brain dysfunction associated with infantile autism. **Method:** They measured regional cerebral blood flow with single photon emission computed tomography (SPECT) and xenon-133 in 21 children with primary autism (according to DSM-III-R criteria). Five cortical brain areas including frontal, temporal, and sensory association cortices were examined in order to test the recent hypothesis of cerebral dysfunction in primary autism. Anatomical references for each subject were obtained with computerized tomography or magnetic resonance imaging and were used to delimit the regions of interest for SPECT analysis. **Results:** When the results from the group with primary autism were compared with an age-matched group of nonautistic children with slight to moderate language disorders (N=14), no cortical regional abnormalities were found. **Conclusions:** It appears that there is no regional cortical dysfunction in primary autism; however, in light of methodological limitations, one cannot exclude the possibility of more localized or subcortical brain dysfunctions in autism.

(Am J Psychiatry 1992; 149:924-930)

Childhood autism is an early and severe developmental disorder characterized by deficits in verbal and nonverbal language and social and cognitive functioning (1; DSM-III-R). Little is known about the neurobiological mechanisms that could underlie this disorder. Brain morphological investigations with computerized tomography (CT) scans in autistic subjects have shown reversed cerebral asymmetries (2) and enlargement of the lateral and third ventricles (3, 4), but failed to find a consistent abnormal pattern in the disorder. Some, but not all, magnetic resonance imaging (MRI) studies have reported a hypoplasia of the cerebellar vermis (5, 6), enlargement of the fourth ventricle (7), and cortical abnormalities compatible with developmental malformations, such as polymicrogyria and macrogyria (8). Although these results strengthen the

hypothesis of brain dysfunction in autism, many questions remain unanswered concerning the localization and the nature of these dysfunctions. In addition, an abnormal process of brain maturation that could lead to autism has yet to be identified.

An in vivo approach to brain function is now available with positron emission tomography (PET) and single photon emission computed tomography (SPECT), which could provide additional information about the autistic disorder. Measurements of regional cerebral blood flow (rCBF), coupled with measurements of brain metabolism at rest (9), permit the study of regional brain activity and could be helpful in localizing a regional brain dysfunction in autism. In addition, the changing metabolic patterns accompanying brain development during normal childhood have been determined (10), opening the way to the investigation of brain maturation in autism. To our knowledge, only three PET studies of cerebral glucose metabolism have been reported in autistic subjects (11-13), and they failed to detect regional abnormalities. Those studies were performed either in adults or in children with a wide age range, and the results were compared with adult values. We believe that functional brain studies of children could be more helpful than those of adults because autistic signs are more pronounced during childhood. In addition, restricting the age range of the children and using an age-matched comparison group

should contribute further to our understanding of brain maturation processes in autism. In the present study we used SPECT and xenon-133, a noninvasive technique appropriate to the study of children, to measure rCBF in 5-11-year-old children with primary autism and compared the results to an age-matched group of nonautistic children.

METHOD

Subjects

Twenty-one children, 12 boys and nine girls, with primary autistic disorder were selected among patients attending a day-care child psychiatry unit of a university hospital. Children from 5 to 11 years of age were included. The mean age was 7.5 years (SD=1.7), and the mean nonverbal IQ was 36.0 (SD=18.5) (range=10-75). Infantile autism was diagnosed according to the criteria in *DSM-III-R*. In order to select children who presented strictly primary autism, we excluded subjects with any of the following criteria: 1) known infectious, metabolic, or chromosomal disease, 2) persistent seizures, 3) identifiable neurological syndromes or focal signs, 4) abnormal EEG, and 5) abnormal CT scan or MRI, except for findings previously described in autism such as moderate ventricle enlargement or hemisphere asymmetry (2, 7). All patients were free of medication for at least 1 month before the SPECT examination.

Each child received an extensive evaluation, including a detailed developmental psychiatric history that used a videotaped psychiatric assessment, psychological and

linguistic tests, pediatric and neurological examination, and audiological assessment. Behavioral, cognition, language, and neurological signs found in each patient are listed in table 1. They were scored according to four different scales previously developed in our laboratory. The Behavior Summarized Evaluation Scale (14) evaluates both autistic symptoms and associated features including eating, sleep, and motor disorders. The development quotient evaluates the cognitive level (15), and development quotient values were classified in five levels of increasing severity: 1) development quotient more than 70, 2) 50-69, 3) 35-49, 4) 20-34, and 5) less than 20. A neurological examination and an electrophysiologic recording (EEG) enabled us to define five levels of neurological involvement (16): 1) no neurological signs, 2) minor signs and/or history of convulsions, 3) unique lesional syndrome and/or paroxysmal anomalies on the EEG, 4) multiple lesional syndromes and/or convulsive seizures, and 5) major impairments or consciousness disorders. Children with a score greater than 2 were excluded from this protocol. Speech disorders were also classified into five levels of increasing intensity (17): 1) appropriate and communicative speech, 2) minor speech abnormalities, 3) moderate speech abnormalities, 4) intense abnormalities of speech, and 5) no communicative speech.

Since rCBF studies are not performed in normal children in our institute for ethical reasons, we selected a group of 14 children, 10 boys and four girls, whose age matched the autistic group and who had undergone a SPECT examination for a slight-to-moderate language disorder, diagnosed as a developmental language disorder (*DSM-III-R* criteria). Their mean age was 8.7 years

(SD=1.5), and the mean nonverbal IQ was 96.1 (SD=12.3) (range=80–125). They had a slight scholastic retardation but did not have behavioral, social impairment, or intelligence deficits.

This study was approved by our ethical committee, and all examinations were performed with the informed consent of the parents.

Procedure

Brain imaging protocol. Brain imaging studies consisted of SPECT and CT or MRI images acquired on the same day for each subject. Performing these studies on the same day ensured that the subject's head was identically positioned for the two examinations by the same investigator. The detailed information from the CT or MRI images allowed us to perform an individual anatomical localization of brain regions in functional SPECT image analysis processes (18).

Functional images. The rCBF measurements were performed with a brain-dedicated SPECT system (Medimatic, Tomomatic 564), using a 1-minute xenon-133 inhalation (740 MBq/liter) and a 4.5-minute image acquisition (19). Autistic children were studied at sleep after premedication (rectal administration of 4 mg/kg of pentobarbital and intramuscular injection of 0.1 mg/kg of droperidol), while comparison children were studied at rest without premedication. Five 20-mm-thick contiguous axial rCBF slices were obtained with an in-plane resolution of approximately 14 mm, and three of these were used in this study (40, 60, and 80 mm above the orbitomeatal line).

Anatomical images. Anatomical images were acquired on an X-ray CT (CT, CGR 9000) for each subject. The CT imaging protocol consisted of ten 9-mm-thick slices acquired parallel to the orbitomeatal line. In addition, four of the autistic children had an MRI brain study (General Electric, MRMAX 0.5T). In these subjects, T₁ sequences were performed and 10 axial slices, 10 mm thick, were obtained.

Regions of interest. Five cortical brain regions from each hemisphere were a priori retained for analysis, on the basis of Mesulam's model of modular and hierarchical cortical organization (20): sensorimotor (including Brodmann's areas 1, 2, 3, 4, and 43 and Broca's area on the left side), visual unimodal association (including Brodmann's areas 20, 21, and 37), auditory unimodal association (Brodmann's area 22, including Wernicke's area on the left side), heteromodal association (Brodmann's areas 7, 39, and 40), and frontal (Brodmann's areas 10, 44, 45, and 46) areas. These cortical brain regions were determined on the three slices of CT or MRI images that corresponded to the levels of the SPECT images. On each CT or MRI slice a 20-mm-thick cortical ribbon was delineated and cut into regions of interest corresponding to the various cortical brain areas; Matsui's anatomical human brain atlas was used for reference (21). The entire set of regions of interest was copied onto the corresponding SPECT slice for rCBF computation, and the rCBF was averaged over

regions of interest belonging to the same cortical brain region on different slices (figures 1 and 2). Depending on the region and on subject head size, a given region could be present on one or more slices, for example, three slices for the frontal cortex and two for the sensorimotor area. This method of region of interest placement has a high interobserver reproducibility with regional intraclass correlation coefficients ranging from 0.973 to 0.995 (18). We did not include subcortical regions in the analysis because of the limitations of attenuation correction with SPECT.

Data Analysis

Mean cortical CBF was calculated as the mean CBF value of the entire cortical ribbon in the three slices. Cortical CBF and rCBF were calculated in absolute values (ml/100 g per minute). The relative values were determined as the regional values divided by the mean cortical CBF (rCBF/cortical CBF). Right-to-left ratios were defined for each region and for the cortical CBF. An anterior-to-posterior ratio was defined as the frontal value divided by posterior rCBF values (heteromodal association and visual unimodal association regions). Statistical analyses were performed on both absolute and relative rCBF values by Student's *t* test in the large cortical brain regions and in each smaller "within-plane" region of interest. In addition, right-to-left and anterior-to-posterior regional indices were analyzed in both groups with paired *t* tests. Correlations among age, clinical features (behavioral, cognitive and language scores), CBF values (regional, mean cortical), and CBF index (right-to-left and anterior-to-posterior ratios) were studied by nonparametric regressions.

Effect of Premedication

The effect of the premedication used to sedate the autistic children was previously assessed in 10 children with neurological disorders. CBF was measured in each of these children on the same day, before and after premedication. Analysis were performed in 10 right and six left hemispheres without CBF abnormalities (four left hemispheres were excluded because of major hypoperfusion). No statistically significant difference was observed between the mean hemispheric CBF before (65.2 ml/100 g per minute, SD=8.8) and after (68.6 ml/100 g per minute, SD=10.7) premedication (paired *t* test). No effects on absolute or relative rCBF values were observed. The mean differences in relative rCBF values before and after premedication ranged from -2% (SD=3.3%) in the left visual unimodal association region to 4.2% (SD=3.2%) in the right heteromodal association region (n.s., Bonferroni's corrected paired *t* test).

RESULTS

Mean cortical blood flow was 70.2 ml/100 g per minute (SD=10.0) in the autistic group and 70.2 ml/100 g

FIGURE 1. Regions of Interest Defined on MRI Images (top) and Registered on Corresponding SPECT Slices (bottom) for 21 Autistic Children and 14 Comparison Children

per minute ($SD=9.5$) in the comparison group. In all regions CBF values were also very similar in autistic and comparison children (table 2). Mean cortical CBF and rCBF did not correlate with age in either the autistic children or the comparison group.

No statistically significant group differences were found for relative values of rCBF (rCBF/cortical CBF) (table 2). Right-to-left and anterior-to-posterior regional indices were similar in autistic and comparison children (tables 3 and 4). No correlation was found among relative CBF values, right-to-left or anterior-to-posterior regional indices, and the clinical features analyzed (behavioral, cognitive, and language scores). Analyses performed on the smaller within-plane regions of interest also failed to reveal any statistically significant abnormalities (data not shown).

DISCUSSION

By measuring rCBF with SPECT and xenon-133 in 21 highly selected children with primary autism, we found no evidence of localized brain cortical dysfunction or abnormal index of brain maturation in this disease;

FIGURE 2. Lateral View of Brain Illustrating Pooling of Regions of Interest Into Five Cortical Brain Regions

rCBF values of autistic children at rest were remarkably similar to those of 14 nonautistic children. Previous

PET measurements of glucose brain metabolism in autistic subjects also failed to find any regional cerebral abnormalities. Rumsey et al. (11) found that glucose utilization was significantly elevated in widespread regions of the brain of 10 adult autistic subjects, but no consistent localized abnormalities were identified. Horwitz et al. (13) confirmed these results but described significantly fewer large positive correlations between pairs of regions in frontal and parietal lobes in 14 adult autistic patients than in an age-matched control group. The only PET study performed in autistic children, from 2 to 18 years of age, reported a normal regional distribution of brain glucose metabolism when compared with adults (12).

The present data not only confirm but also extend those results for the following reasons. First, the global and regional CBF values in a large group of 5–11-year-old autistic children were similar to those of an age-matched comparison group but were significantly higher than those of normal young adults (mean age=22 years) studied with the same technique in our laboratory (51.0 ml/100 g per minute, SD=7.7) (Raynaud et al., unpublished data) and previously described by others (22). It is interesting that the mean CBF values in the present study (autistic group: 70.2 ml/100 g per minute, SD=10.0; comparison group: 70.2 ml/100 g per

minute, SD=9.5) are extremely close to those reported in normal 7–15-year-old children (71.0 ml/100 g per minute, SD=9.9) (23). These data confirm the finding that CBF is higher in children than in adults, as is cerebral glucose metabolism (12; Raynaud et al., in preparation) and may indicate that the maturation process responsible for a transient CBF increase during childhood is not altered in autistic children. Chugani et al. (10) showed that regional distribution of glucose metabolism is also age dependent in early childhood but that the adult pattern is present from the age of 1 year.

Second, three hypotheses of brain dysfunction in autism are largely supported by clinical, cognitive, neurophysiological, and neuroradiological data: a frontal dysfunction (24–26), a left-right asymmetry (27, 28), and abnormalities in cortical areas specialized in the processing of sensorial information (29–31). In order to test these hypotheses, we a priori chose to pool regions of interest into larger brain areas on the basis of the modular and hierarchic organization of the cerebral cortex proposed by Mesulam (20). In addition, regions of interest were determined on individual CT or MRI images to ensure accurate localization of our regional CBF measurements. We believe our method is of particular importance in studies of children, since the direct placement of regions of interest

on CBF images can be more problematic than in adults because of the difficulty in delimiting cortical borders. However, this method risks missing smaller focal areas of abnormalities. Yet, such abnormalities were not detected in the autistic or in the comparison group by blind visual analysis of individual images. Furthermore, the quantitative analysis performed on smaller within-plane regions of interest did not reveal any significant abnormalities.

Third, the present data obtained in children with primary autism constitute a valuable foundation for investigating the potential diagnostic value of SPECT for the detection of secondary autism. This is of particular interest considering the recent report of prefrontal and temporoparietal hypoperfusion in seven girls with Rett's syndrome (32), a condition that is still often misdiagnosed as primary autism.

The results of the present study, however, must be considered in the light of some technical and methodological limitations. The relatively poor spatial resolution of our device precludes a valid analysis of small brain areas that might be of crucial importance in autism. For example, the cerebellar cortex, especially the cerebellar vermis, which has been associated with autism (6), cannot be clearly distinguished from the occipital cortex in children because of a partial volume effect. Similarly, rCBF in internal temporal structures such as hippocampus and amygdala, which are of primary importance in the final integration of sensorial information and in behavior elaboration (33), could not be measured. Further, we did not analyze subcortical structures because of the lack of correction for auto-attenuation, a current technical limitation of SPECT.

For ethical reasons we do not measure rCBF in normal children in our institution. Therefore, we had the choice of using comparison values obtained from either a highly selected group of subjects with a different developmental disorder or a less homogeneous group of nonautistic children studied for various neurological signs. For these reasons, we selected as comparison subjects a group of children with mild language disorders. First, comprehensive comparisons between autistic and dysphasic children have shown marked clinical differences between both groups. Thus, it seems unlikely that an identical developmental abnormality is involved in both pathologies (34). Second, although rCBF measurements in children with language disorders show an rCBF pattern different from that of normal children (22, 35), a careful examination of published data shows that most abnormalities are apparently related to attention deficit disorder (a feature that was excluded in our dysphasic children) rather than to the language deficits. In addition, the abnormalities described are quantitatively moderate and localized primarily in subcortical structures. Since our group of children with mild language disorder participated in an independent research protocol carried out at the same time as the present work, these children were also screened to exclude any other neurological or psychiatric disorders. Consequently, we believe that our comparison of autistic and

dysphasic children should have detected rCBF abnormalities specifically related to autism.

Finally, the possible effects of the premedication administered to the autistic children but not to the comparison subjects was examined, since many sedative drugs are known to decrease CBF and cerebral metabolism (36, 37). One might speculate that the premedication might have masked elevated CBF values, which could be expected since an increase in global cerebral glucose utilization has been reported in adult autism (11). However, this remains unlikely because we found that the premedication did not alter CBF in children.

In summary, rCBF values measured at rest were normal in 5–11-year-old primary autistic children. This furnishes a basis for the future investigation of secondary autism with SPECT. It does not, of course, rule out brain abnormalities that may become detectable in the near future through use of more sophisticated stimulation rCBF studies or more specific neurochemical tracers.

Objective: The authors' goal was to examine subjective and objective predictors of post-traumatic stress disorder (PTSD). **Method:** Hospitalized burn patients were assessed 1 week after injury with both objective predictors (percent of burned area and facial disfigurement) and subjective predictors (emotional distress and perceived social support). The patients were then assessed 2, 6, and 12 months later for development of PTSD. **Results:** Among 51 patients, 18 (35.3%) met PTSD criteria at 2 months. High rates of PTSD were also found at 6 months (N=16, 40.0% of the 40 available patients) and 12 months (N=14, 45.2% of the 31 available patients). PTSD was predicted by subjective variables assessed at baseline, but patients with more severe burns were not more likely to develop PTSD. **Conclusions:** The DSM-III-R diagnosis of PTSD relies on an objective evaluation of the stressor's severity. The prospective data in this study support those who argue that evaluations of the severity of the stressor might also take into account subjective factors.

(Am J Psychiatry 1992; 149:931-935)

Although the emotional effects of severe trauma were recognized by Charcot, Freud, Janet, and others, the diagnosis of these effects has been inconsistently defined (1-3). In *DSM-I*, "gross stress reaction" excluded patients with other psychopathology, *DSM-II* deleted this category altogether, and *DSM-III* introduced explicit criteria for posttraumatic stress disorder (PTSD), but then *DSM-III-R* narrowed the stressor criterion and added that the symptoms must have a duration of at least 1 month.

One reason for this inconsistency has been the paucity of prospective data. Most studies have not assessed subjects immediately after the trauma and instead have evaluated symptomatic groups months or years after the stressful event. Such methods not only raise questions about sample bias and retrospective reporting but also preclude determining if the development of PTSD is related to the individual's emotional state at the time of the trauma. Further, studies have not quantified the stressor to determine if its severity predicts PTSD.

The DSM-IV Task Force is considering whether the current criteria for PTSD should once again be modified, especially regarding the definition of the stressor criterion. The *DSM-III* criterion ("a recognizable stressor that would evoke significant symptoms of distress in almost everyone") may have been too broad

and may have trivialized the concept, whereas the *DSM-III-R* criterion ("an event outside the range of usual human experience") may be so narrow that it wrongfully excludes some patients with posttraumatic symptoms. Also at issue is whether the stressor criterion should include an assessment of the individual's subjective response to the trauma, such as emotional distress and perceived helplessness. Finally, there is debate as to whether avoidant mechanisms reliably and validly characterize the phenomenology of PTSD. Perhaps social withdrawal and numbing of responsiveness ("emotional anesthesia") are not characteristic and only intrusive criteria (e.g., "flashbacks") should be used diagnostically.

In response to the call for prospective data to address these issues (2-5), we evaluated patients shortly after hospitalization for a burn injury and followed a representative sample for 1 year to determine the development of PTSD. We chose to study burn patients because the severity of the stressor can be objectively quantified and has a wide variance, because the distress associated with the trauma can be assessed shortly after the event, and because burn injury requiring hospitalization contains those elements presumed to be associated with PTSD (threat of disability or death; exposure to overwhelming stimuli; suddenness, unexpectedness, and unpreparedness; loss of loved ones and/or property; and direct involvement with the stressor) (6).

METHOD

Every adult patient admitted to our hospital's burn center was approached within the first week of hospi-

talization. If the patient was able and willing to give informed consent, four subjective variables were measured: 1) emotional distress as measured by the Profile of Mood States (POMS) (7), which includes an assessment of state anxiety and helplessness, 2) perceived social support as measured by the Interpersonal Support Evaluation List (8), 3) intrusive thoughts during the past week about the burn injury as measured by the Impact of Event Scale (9), and 4) avoidant thoughts about the injury as measured by the Impact of Event Scale (9). The selection of these four subjective predictors of PTSD was based on a review of existing literature (2, 4–6, 10). Many patients are unable to write during the first few weeks following their injuries. For consistency in data collection, investigators read the questionnaires to all patients and marked their responses on the standardized instruments.

Objective severity of the stressor was assessed by using two measures: percent of total body surface area of the burn and percent of patients with facial disfigurement. Although not the primary focus of the study, we also estimated psychopathology before the burn by reviewing charts and interviewing available informants about any history of alcoholism, drug abuse, psychosis, and psychiatric hospitalization.

Patients were subsequently assessed at 2, 6, and 12 months after their burn injury. A clinical rating of PTSD was obtained by using the Structured Clinical Interview for DSM-III-R (SCID) (11). To examine the concurrent association between PTSD and psychological factors and to determine if these psychological factors predicted future PTSD, patients then completed the POMS and the Impact of Event Scale. The interviewers were blind to responses on these self-report measures. Patients geographically distant or otherwise unable or unwilling to attend follow-up assessments were clinically rated by a 30-minute telephone SCID interview and returned questionnaires by mail.

Logistic regression analyses were used to determine the extent to which baseline subjective and objective measures predicted PTSD at 2-month–12-month follow-up and to determine whether scores on the POMS and the Impact of Event Scale at 2-month and 6-month follow-up predicted PTSD at later assessments. Analyses of variance examined concurrent relationships between PTSD and the psychological measures (POMS and the Impact of Event Scale intrusive and avoidant thoughts). Since others (12) have reported a correspondence between PTSD and Impact of Event Scale cutoff scores (greater than 19 on both intrusive and avoidant thoughts about the injury), we examined the specificity and sensitivity of these cutoffs in our sample. Finally, we explored whether PTSD was predicted by sociodemographic variables and estimates of premorbid psychopathology.

RESULTS

Two-month follow-up data were obtained for 34 men and 17 women; 22 (43%) of these 51 patients were white,

16 (31%) were black, 11 (22%) were Hispanic, and two (4%) were "other"; 23 (45%) were married, 16 (31%) were single, and 12 (24%) were divorced or separated; 24 (47%) were skilled laborers, nine (18%) were homemakers, eight (16%) were unemployed, two (4%) were professionals, and eight (16%) did not provide data on their occupation. A history of alcoholism was documented in 12 (24%), other drug abuse in nine (18%), and psychosis or psychiatric hospitalization in eight (16%). Burns were due to flame injury ($N=38$, 75%), scalding ($N=11$, 22%), or chemical exposure ($N=2$, 4%).

Six-month follow-up data were available for 40 patients, and 12-month data were available for 31 patients.

An additional 78 patients were assessed within the first week of hospitalization but were lost to follow-up by 2 months after the injury. Two of these patients had died; 68 (89%) of the remaining 76 could not be located after discharge. (A change of address is a common consequence of burn injury and its associated physical, familial, and residential disruption.) Eight (11%) of the dropouts were located but refused to participate at the 2-month follow-up. At no follow-up assessment was attrition significantly related to age, sex, race, marital status, PTSD at a previous assessment, or hypothesized predictor variables (e.g., severity of distress or burn).

To assess the relative contributions of the independent variables (social support, body surface area burned, general distress, intrusive and avoidant thoughts, facial disfigurement) assessed at baseline in predicting PTSD, a forward stepwise logistic regression analyses was performed for each assessment time.

As shown in table 1, patients with smaller burns were more likely to meet criteria for PTSD at the 2-month assessment. PTSD at this assessment was also predicted by less perceived emotional support (Interpersonal Support Evaluation List) and greater emotional distress (POMS). Regarding subjective variables, less perceived social support at baseline (mean=7.2 days, $SD=1.1$, after burn injury), the first variable selected for inclusion in the regression model, predicted acute PTSD at 2-month follow-up (mean=10.5 weeks, $SD=1.9$, later). According to model chi-square (table 1), this variable made a significant improvement over the constant in predicting PTSD in this group of patients. Severity of emotional distress at baseline contributed to the prediction of acute PTSD (table 1). The severity of intrusive or avoidant thoughts during the first week of hospitalization did not predict acute PTSD. Regarding objective variables, the presence of facial disfigurement did not predict PTSD. Eleven (22.4%) of the 18 patients with PTSD at 2 months and 16 (30.6%) of the 33 patients without PTSD at 2 months had facial disfigurement at baseline. More extensive burn injury was also not associated with the development of PTSD. However, patients with smaller burns were significantly more likely to meet criteria for acute PTSD (table 1).

In the final model, the goodness-of-fit chi-square of 40.8 ($df=43$, $p=0.6$) had a high probability of occurrence; i.e., the null hypothesis that the model's predictions differ from the observed data was not confirmed.

Avoidant thoughts	13.3	10.5	10.6	10.4	—		—		—

TABLE 2. Psychological Predictors of PTSD 6 Months After Burn Injury

Variable at 2 Months	Patients With PTSD at 6 Months (N=16)		Patients Without PTSD at 6 Months (N=24)		ANOVA		Logistic Regression		
	Mean	SD	Mean	SD	F (df=1, 38)	p	χ^2 Improvement (df=1)	p	β
POMS	8.1	4.7	2.9	4.9	8.8	<0.01	8.3	<0.01	0.11
Impact of Event Scale									
Intrusive thoughts	20.8	9.4	6.7	5.8	26.0	<0.01	8.7	<0.01	0.18
Avoidant thoughts	15.5	11.5	5.3	6.2	9.9	<0.01	—		—

TABLE 3. Psychological Predictors of PTSD 12 Months After Burn Injury

Variable at 6 Months	Patients With PTSD at 12 Months (N=14)		Patients Without PTSD at 12 Months (N=17)		ANOVA		Logistic Regression		
	Mean	SD	Mean	SD	F (df=1, 29)	p	χ^2 Improvement (df=1)	p	β
POMS	12.1	9.5	2.4	3.9	14.5	<0.001	9.2	<0.01	0.18
Impact of Event Scale									
Intrusive thoughts	22.1	12.3	8.1	10.0	13.9	<0.001	—		—
Avoidant thoughts	16.4	12.3	2.9	3.8	18.4	<0.001	3.3	<0.05	0.12

Thus, a regression model that predicts PTSD on the basis of social support, body surface area burned, and general emotional distress is a good predictive model.

In addition to predicting acute PTSD, social support was also a significant predictor of chronic PTSD at both 6 months (mean=26.5 weeks, SD=3.4) and 12 months after injury (mean=54.7 weeks, SD=3.4). Social support yielded a model chi-square of 4.9 (df=1, $p<0.03$) at 6 months and a model chi-square of 5.0 (df=1, $p<0.03$) at 12 months. None of the other hypothesized variables at baseline predicted PTSD at 6 or 12 months.

Tables 2 and 3 present the results of subsequent psychological assessments at 2 months and 6 months as predictors of PTSD. Severity of emotional distress at the previous follow-up appointment predicted the presence of PTSD at the next assessment. Severity of intrusive thoughts at 2 months predicted chronic PTSD at 6 months (table 2), and severity of avoidant thoughts at 6 months predicted chronic PTSD at 12 months (table 3).

As indicated in table 4, severity of emotional distress and both intrusive and avoidant thoughts were significantly associated with concurrent PTSD at all three fol-

low-up assessments. The association between PTSD and both intrusive and avoidant thoughts about the injury on the Impact of Event Scale cutoff scores was generally high. The cutoff for intrusive thoughts about the burn injury on the Impact of Event Scale correctly identified 79%, 100%, and 83% of those with PTSD and 81%, 78%, and 61% without the diagnosis at 2-, 6-, and 12-month follow-up, respectively, and the cutoff for avoidant thoughts about the injury on the Impact of Event Scale correctly identified 78%, 89%, 100% with PTSD and 74%, 71%, and 61% without the diagnosis.

Exploratory analyses found no significant relationship between future PTSD and sex, age, race, marital status, or estimates of premorbid psychopathology. To our knowledge, no patient received psychiatric treatment for the emotional impact of the burn trauma.

DISCUSSION

By assessing burn patients during the first week of hospitalization and then following a representative

TABLE 4. Psychological Variables and Concurrent Development of PTSD at 2, 6, and 12 Months After Burn Injury

Avoidant thoughts	14	13.7	13.5	17	3.4	6.3	6.8	1, 25	0.001

sample for 1 year, we were able to examine what role subjective and objective factors play in the development of PTSD. We found that less perceived social support shortly following the trauma predicted PTSD at all three follow-up assessments, whereas more severe injury did not predict PTSD. Indeed, patients with smaller burns were more likely to meet criteria for acute PTSD.

One must be cautious in generalizing the results from a single study, particularly one in which all patients had experienced the considerable stressor of a burn injury. Nonetheless, this report does provide data for the long-standing debate about whether the development of PTSD is relatively more dependent on subjective factors than on the severity of the stressor. Our data lend support to the view that the individual's psychological state immediately following the event is more predictive of outcome than the degree of trauma (2, 13). These findings are pertinent to the deliberation over the inclusion of a subjective component for the stressor criterion in *DSM-IV*. The addition of subjective experience would include in the diagnosis those who may experience less severe stressors as overwhelming in the context of limited social support and its associated helplessness.

In regard to other suggested changes in the diagnostic criteria for PTSD, our data would support maintaining avoidant phenomenology. Like intrusive thoughts, endorsements of avoidant thoughts about the injury on the Impact of Event Scale were significantly associated with PTSD at each assessment.

Our findings may also be helpful in regard to clinical care, alerting clinicians about the high frequency of PTSD in burn patients and the emotional distress related to this disorder as measured by the POMS. At least a third of the patients we followed developed PTSD during the first year after the burn injury. Although patients who could not be located did not differ significantly from those who were followed on any variable measured at baseline, the rate of attrition precludes determining the prevalence of PTSD in this population. We doubt, however, that our reported high

rates are inflated. On the contrary, in the light of the association between less social support and future PTSD, we suspect that the prevalence of PTSD may be even higher among those who experienced a change of address as a result of residential fire and familial loss or disruption.

We were surprised that none of our patients reported seeking treatment for the residual emotional impact of their burn injuries. Possibly, the socioeconomic status of our sample made psychiatric treatment less accessible or affordable, but another possibility is that the avoidant ("numbing") mechanisms associated with PTSD impeded patients from seeking help or spontaneously describing their psychological symptoms to clinicians and others. Since we found that the severity of intrusive and avoidant thoughts after discharge was not only associated with concurrent PTSD but also helped predict future PTSD, those who provide follow-up surgical care and physical rehabilitation might consider administering the Impact of Event Scale at outpatient appointments. This rapidly scored self-report instrument requires less than 5 minutes to complete and could help guide early detection of current or future PTSD for further evaluation and psychiatric referral. Among our sample, the designated cutoff scores had adequate sensitivity and specificity for a screening measure.

More problematic is the prediction of PTSD during hospitalization while the patient is still in the throes of acute trauma and its treatment. Although counterintuitive, our findings would suggest that clinicians not use severity of the injury as a predictor. Similarly, severity of intrusive and avoidant thoughts during the first week after the injury was not associated with the development of PTSD, suggesting that such mental processes immediately after a severe trauma may be normal and, consistent with a modification in *DSM-III-R*, should be defined as pathological only if they persist. On the other hand, since we found that lower scores on the Interpersonal Support Evaluation List predicted PTSD throughout the first year, perhaps early supportive psychother-

apy should be targeted toward those burn patients who feel more socially isolated.

A limitation of this study was the absence of standardized assessment of psychopathology before the trauma. Although the estimated rates of previous alcoholism, drug abuse, psychosis, and psychiatric hospitalization suggest greater psychopathology in our sample than in community samples (14), this history did not predict PTSD, and most patients (56%) did not have an available history of these psychiatric disorders before their burns, supporting the findings of others that PTSD can occur in previously "normal" individuals (1, 2, 10). Despite this limitation, the prompt evaluation soon after the trauma, the quantifiable measures of both objective and subjective variables, and the prospective design have advantages over most other studies in examining variables that help predict, mediate, and define PTSD.

Effectiveness of a Meditation-Based Stress Reduction Program in the Treatment of Anxiety Disorders

Jon Kabat-Zinn, Ph.D., Ann O. Massion, M.D., Jean Kristeller, Ph.D.,
Linda Gay Peterson, M.D., Kenneth E. Fletcher, Ph.D., Lori Pbert, Ph.D.,
William R. Lenderking, Ph.D., and Saki F. Santorelli, Ed.D.

Objective: This study was designed to determine the effectiveness of a group stress reduction program based on mindfulness meditation for patients with anxiety disorders. **Method:** The 22 study participants were screened with a structured clinical interview and found to meet the DSM-III-R criteria for generalized anxiety disorder or panic disorder with or without agoraphobia. Assessments, including self-ratings and therapists' ratings, were obtained weekly before and during the meditation-based stress reduction and relaxation program and monthly during the 3-month follow-up period. **Results:** Repeated measures analyses of variance documented significant reductions in anxiety and depression scores after treatment for 20 of the subjects—changes that were maintained at follow-up. The number of subjects experiencing panic symptoms was also substantially reduced. A comparison of the study subjects with a group of nonstudy participants in the program who met the initial screening criteria for entry into the study showed that both groups achieved similar reductions in anxiety scores on the SCL-90-R and on the Medical Symptom Checklist, suggesting generalizability of the study findings. **Conclusions:** A group mindfulness meditation training program can effectively reduce symptoms of anxiety and panic and can help maintain these reductions in patients with generalized anxiety disorder, panic disorder, or panic disorder with agoraphobia.

(Am J Psychiatry 1992; 149:936–943)

Self-regulatory behavioral strategies, used alone or as adjuncts to other behavioral or medication regimens, may offer a unique approach to treating anxiety disorders. Three major self-regulatory strategies—meditation, relaxation, and biofeedback—are currently used in clinical practice for the treatment of anxiety. Research suggests that all three play a role in reducing both physiological and psychological components of

anxiety in normal populations and that the latter two techniques are effective in anxious populations, although with variable efficacy (1–6).

The research on meditation techniques has been largely limited to nonpsychiatric populations (7). To our knowledge, there are no studies of the effectiveness of meditation for patients with anxiety disorders as delineated by DSM-III or DSM-III-R criteria (8). Two controlled studies (9, 10) used meditation for patients with anxiety neurosis as defined by DSM-II criteria, but both lacked standardized diagnostic procedures. There was one uncontrolled study of patients diagnosed as having anxiety neurosis (11). None of these studies used a structured clinical interview for diagnosis. All of them investigated variants of one particular type of meditation, namely, transcendental meditation, in which the practitioner focuses on a mantra—a word or phrase repeated silently to achieve a meditative state.

In general, these studies suggested that transcendental meditation may be as effective as other behavioral techniques, such as biofeedback or relaxation, in the treatment of anxiety. Another uncontrolled study (12) investigated mindfulness meditation as an adjunct to psychotherapy for patients with a wide range of psychiatric disorders, excluding schizophrenia and other psy-

choses. In that study, Kutz et al. found that according to both the patients' self-assessments and the therapists' assessments, there was moderate to marked improvement in a variety of psychological symptoms, including anxiety, from before to after treatment.

The lack of diagnostic assessment according to standardized diagnostic criteria in previous studies and the widespread practice of studying nonclinical populations (e.g., college students) limit the applicability of research findings regarding the clinical effectiveness of meditation. Moreover, the majority of the studies of the effects of meditation on anxiety have relied solely on measures of state-trait anxiety to determine outcome. Such measures do not adequately assess the presence of panic attacks or avoidance behavior and may fail to capture the complexity of clinically significant anxiety symptoms.

The present pilot study was devised to address some of the shortcomings of previous research that investigated the relation between meditation training and anxiety reduction. The study was conducted in conjunction with a well-established outpatient program for stress reduction and relaxation that involves intensive training in mindfulness meditation (13, 14), with emphasis on its practical applications in coping with stress and in enhancing adaptive health behaviors. Like other forms of meditation such as transcendental meditation, mindfulness meditation helps practitioners to cultivate greater concentration and relaxation (15). It differs specifically from transcendental meditation by training practitioners to attend to a wide range of changing objects of attention while maintaining moment-to-moment awareness (mindfulness), rather than restricting one's focus to a single object such as a mantra (16) (see the Method section for an operational definition). The choice of mindfulness as the primary meditative approach was due to its immediate applicability to a great variety of present-moment experiences. This orientation lends a quality of "ordinariness" to the intervention that makes it more acceptable and accessible to a wide range of people with different life stressors and different medical disorders (17).

The stress reduction and relaxation program serves a broad spectrum of patients with both physical and psychological disturbances (18). Previous studies have shown that participation in the program results in reductions in both physical and psychological symptoms of patients in many diagnostic categories. Chronic pain patients participating in the program reported markedly reduced levels of state anxiety (as measured with the Symptom Checklist-90-Revised) during the intervention period—levels that were maintained over a 4-year follow-up period (17, 19, 20). Similar changes were reported over a 2-year follow-up period by patients with stress-related medical disorders (Kabat-Zinn, unpublished manuscript).

The specific objectives of the present investigation were 1) to conduct a prospective outcome study, with a repeated measures design, to test the efficacy of treating patients diagnosed with anxiety disorders according to

DSM-III-R criteria in a well-established, meditation-based outpatient stress reduction program and 2) to examine whether variables at intake were predictive of outcome at follow-up.

METHOD

Potential subjects were selected from among all patients referred to the stress reduction and relaxation program in two consecutive cycles (spring and fall of 1988). The Symptom Checklist-90-Revised (SCL-90-R) (21) and the Medical Symptom Checklist (17) were administered to all patients referred to the program, as part of the intake evaluation. Those who scored above the 70th percentile on the anxiety subscale of the SCL-90-R and reported more than 10 anxiety-related symptoms (out of 37 possible symptoms) on the Medical Symptom Checklist were invited to take part in a formal screening interview to assess their appropriateness for inclusion in the study. A referral diagnosis of panic attacks or anxiety also qualified an individual to be invited to participate in the screening procedure for the study. Patients who met the study criteria and who agreed to participate were then interviewed by either a psychologist or a psychiatrist trained in administering the Structured Clinical Interview for *DSM-III-R* (SCID) (22). Diagnoses were determined after review of the SCID data by the two psychologists (J.K. and L.P.) and two psychiatrists (A.O.M. and L.G.P.) who conducted the individual screening evaluations. Only the patients who met the formal diagnostic criteria for generalized anxiety disorder or panic disorder with or without agoraphobia were included in the study. Individuals were excluded if they had other primary psychiatric diagnoses, any disorder with psychotic symptoms, any endocrine disorder, or significant current alcohol or substance abuse. Because of the small sample size and the pilot nature of the study, patients taking anxiolytic or other medications ($N=12$) were not excluded. Medication type and usage were assessed for all patients during the study.

In the two cycles of the program from which patients were recruited for this study, 192 (60%) of 321 patients satisfied the initial screening criteria of the SCL-90-R and the Medical Symptom Checklist. However, for logistical reasons and because this was a pilot study, only 44 patients were invited to undergo further screening, of whom 32 completed the evaluation. Of these, 24 met the *DSM-III-R* criteria for generalized anxiety disorder or panic disorder with or without agoraphobia according to the SCID. Of the eight excluded patients, four had other primary psychiatric diagnoses and four had no psychiatric disorder. Two of the 24 subjects did not complete the program and were not included in the analysis of outcome. Both of these individuals had psychiatric diagnoses of generalized anxiety disorder.

Because of the exploratory nature of the study, we used a repeated measures design with patients serving as their own controls on multiple pretreatment and post-

treatment measures. In addition, study participants were compared on the SCL-90-R and Medical Symptom Checklist with other patients who met the initial screening criteria and were enrolled in the stress reduction and relaxation program during the same time period but who were not invited to take part in the study. This second group of patients (termed "nonstudy participants") received the same meditation intervention but did not undergo screening or the weekly assessments that the study subjects underwent.

Subjects who met the diagnostic criteria and agreed to participate in the study were evaluated with both self-rating scales and ratings of trained interviewers. Data on the following measures were gathered by telephone interview at weekly intervals from the time of recruitment through the end of treatment and at monthly intervals for 3 months after treatment: the Beck Anxiety Inventory (used by special permission of Jeffrey Sugerman, Ph.D., Psychological Corp., personal communication), the Beck Depression Inventory (23), and ratings of the frequency and severity of panic attacks. The length of time between recruitment and the start of treatment in which data were collected varied according to when subjects were recruited into the study relative to the beginning of the program (range=1-8 weeks).

In addition to these assessments, a more extensive assessment battery was administered four times: at recruitment into the study, at the start of the program (pretreatment), at completion of the program (posttreatment), and at 3-month follow-up. This battery consisted of the Hamilton Rating Scale for Anxiety (24) (as modified by DiNardo and Barlow [25] to include a separate rating scale for symptoms present during panic attacks, yielding the Hamilton panic score), the Hamilton Rating Scale for Depression (26), the Fear Survey Schedule (27), and the Mobility Inventory for Agoraphobia (28). At recruitment patients were also asked to rate on a 5-point scale their expectancy of improvement due to the treatment. A compliance questionnaire was administered at the end of treatment and at follow-up. Eight subjects entered the study so close to the beginning of the treatment intervention that only pretreatment, posttreatment, and follow-up measures were obtained.

The Hamilton anxiety and depression rating scales were administered at recruitment by the same clinicians who administered the SCID. Subsequent Hamilton assessments were administered to all subjects by one trained interviewer. To minimize bias in data collection related to expectancy of change, scoring was done after all data were collected.

The stress reduction and relaxation program is a highly structured training program in mindfulness meditation and its applications, described in detail elsewhere (14, 17-20). It takes the form of an 8-week-long course in which participants attend weekly 2-hour classes and, in addition, a 7.5-hour intensive and mostly silent "meditation retreat" session in the sixth week. During each 8-week cycle, five separate but par-

allel classes are offered. Each is led by one instructor who stays with that group for the duration of the course. Each class has approximately 30 participants with a wide range of medical and psychological disorders. During classes and for homework, participants practice a range of different formal and informal meditation techniques (14, 17). These experiences are discussed weekly in the classes. The 22 subjects in this study were distributed among five of the 10 classes held during that period. The exposure of these subjects differed from that of the remainder of the program participants only in their involvement in the additional assessment protocol required for the study. Four program instructors conducted classes in this study. The instructors did not know which patients were in the study, nor did they know the patients' DSM-III-R diagnoses.

We used repeated measures analysis of variance (ANOVA) to compare the recruitment, pretreatment, posttreatment, and 3-month follow-up scores of the subjects for whom all data points were available, with computation of appropriate contrasts. Matched *t* tests were used to calculate intervention effects between the pretreatment and posttreatment assessments for the entire sample. Intergroup comparisons of compliance and expectancy measures were done with standard *t* tests. Variables expected to predict outcome were studied with ANOVA. We plotted the weekly scores of all subjects to examine the course of change, but formal single-subject analyses are not included in this report because of the consistency and strength of the group effects. In addition, after accounting for pretreatment scores with the regression technique described by Cohen and Cohen (29), we compared posttreatment scores of the subjects receiving medication with those of the subjects taking no medication. Finally, we used *t* tests to compare the study participants and nonstudy participants in the program on pretreatment and posttreatment SCL-90-R scores, Medical Symptom Checklist scores, and change scores.

RESULTS

Of the 22 study participants who completed the program, 10 had panic disorder with agoraphobia, four had panic disorder without agoraphobia, and eight had generalized anxiety disorder as the primary psychiatric diagnosis. Seventeen subjects had more than one psychiatric diagnosis; 14 had other anxiety disorders and eight had diagnoses of major depressive episode (six concurrent). The average duration of their anxiety disorders was 6.5 years (range=3 months to 28 years). Eleven patients were taking medication for their anxiety disorders at intake, and 11 were taking no medication for anxiety.

The subjects' ages ranged from 26 to 64 years, with an average of 38 years. There were five men and 17 women. Eighteen of the subjects were married, two were single, and one was separated (data on one subject were missing).

ilton Rating Scale for Anxiety, the Hamilton Rating Scale for Depression, the Beck Anxiety Inventory, the Beck Depression Inventory, the Fear Survey Schedule, and the Mobility Inventory for Agoraphobia of the subjects with complete data at the four primary assessment points are shown in table 1. They were in the moderate to severe range on both the Beck and the Hamilton anxiety scales and in the mild to moderate range on the Beck and Hamilton depression scales.

At recruitment, nine individuals reported one or more panic attacks in the previous week (range=1–3), with a mean Hamilton panic score of 26.11 (SD=11.25, range=6–40). At pretreatment assessment, 13 individuals reported at least one panic attack in the previous week (range=1–2), with a mean Hamilton panic score of 24.46 (SD=8.71, range=11–34). At pretreatment the mean SCL-90-R general severity index score of the 22 subjects was 1.10 (SD=0.70, range=0–3) and the mean SCL-90-R anxiety score was 1.61 (SD=1.05, range=0–3).

Repeated measures ANOVA indicated that among subjects for whom scores at all four primary assessment points were available, the Hamilton and Beck anxiety and depression scale scores showed small, statistically nonsignificant reductions from baseline to pretreatment, highly significant decreases over the course of the intervention (pretreatment to posttreatment), and maintenance of these changes from posttreatment to follow-up (table 1). Comparisons with matched *t* tests at pretreatment and posttreatment time points for all subjects, not just those with complete data at all time points, showed comparable results, with mean pretreatment and posttreatment scores, respectively, of 25.86 (SD=10.56) and 17.10 (SD=9.31) on the Hamilton anxiety scale ($t=5.18$, $df=20$, $p < 0.001$) and 30.85 (SD=8.81) and 23.85 (SD=6.65) on the Hamilton depression scale ($t=4.88$, $df=19$, $p < 0.001$). Mean pretreatment and posttreatment scores, respectively, were 20.32 (SD=12.05) and 7.09 (SD=8.20) on the Beck Anxiety Inventory ($t=6.14$, $df=21$, $p < 0.001$) and 16.18 (SD=10.33) and 8.18 (SD=8.53) on the Beck Depression Inventory ($t=4.65$, $df=21$, $p < 0.001$). These represented mean reductions of 34%, 23%, 65%, and 49%, respectively,

on the four scales. Twenty of the 22 subjects showed marked improvement in scores on the Beck and Hamilton anxiety and depression scales.

The means of the subjects' weekly ratings of anxiety and depression on the respective Beck scales are presented in figures 1 and 2. These show elevated levels before treatment, a significant decline during treatment to a relatively low level by the end of treatment, and maintenance of the lower posttreatment level over 3 months of follow-up. Scores for "accompanied" on the Mobility Inventory for Agoraphobia showed a similar pattern of improvement. However, scores for "unaccompanied" on that inventory and scores on the Fear Survey Schedule improved as much from recruitment to pretreatment assessment as from pretreatment to posttreatment assessment (table 1).

Of the 13 patients who reported at least one panic attack in the preceding week at pretreatment assessment, five reported one panic attack in the previous week at posttreatment assessment (mean Hamilton panic score=22.0, SD=8.40, range=13–34). At 3-month follow-up, three of the original 13 patients reported one attack in the previous week (mean Hamilton panic score=18.0, SD=6.24, range=11–23). This was a statistically significant decrease in the number of individuals reporting panic attacks from pretreatment to posttreatment to follow-up assessment (Cochran's $Q=14.60$, $df=2$, $p < 0.001$, $N=20$). Within this group, the individuals whose primary psychiatric diagnosis was panic disorder with or without agoraphobia also showed a statistically significant linear decrease from pretreatment to posttreatment to follow-up (Cochran's $Q=12.67$, $df=2$, $p < 0.005$, $N=13$).

In both groups there was a significant decline in Hamilton panic scores between pretreatment and posttreatment assessments. For the subjects who reported at least one panic attack at pretreatment assessment ($N=13$), the mean pretreatment Hamilton panic score was 24.46 (SD=8.71) and the mean posttreatment Hamilton panic score was 8.46 (SD=12.15) ($t=4.75$, $df=12$, $p < 0.001$). For the panic disorder subset ($N=11$), the mean pretreatment Hamilton panic score was 24.64

FIGURE 1. Mean Beck Anxiety Inventory Ratings Before, During, and After Treatment of Patients in a Meditation-Based Stress Reduction Program^a

^aThe numbers of subjects for successive assessments were as follows: pretreatment, 4, 5, 7, 11, 12, 16, 21; treatment, 20, 22, 22, 21, 22, 21, 21, 19; posttreatment, 21, 19, 21.

FIGURE 2. Mean Beck Depression Inventory Ratings Before, During, and After Treatment of Patients in a Meditation-Based Stress Reduction Program^a

^aThe numbers of subjects for successive assessments were as follows: pretreatment, 4, 5, 7, 11, 12, 17, 21; treatment, 20, 22, 21, 21, 22, 21, 22, 19; posttreatment, 21, 20, 21.

(SD=8.30) and the mean posttreatment Hamilton panic score was 8.36 (SD=12.68) ($t=4.07$, $df=10$, $p<0.005$). The mean number of panic attacks registered on the Hamilton anxiety scale and their severity also declined significantly between pretreatment and posttreatment assessments in both groups, and these declines were maintained at 3-month follow-up (data not shown).

The pretreatment and posttreatment scores of the subjects receiving psychotropic medication did not differ significantly from those of the subjects not receiving medication during the study. Twelve patients were taking medication for anxiety before treatment and 13 after treatment; 11 were taking medication at follow-up. Two patients were able to decrease their use of medication between the posttreatment and follow-up assessments, and one increased the use of medication during the same period.

The pretreatment and posttreatment scores on the SCL-90-R and the Medical Symptom Checklist of the study participants in the stress reduction and relaxation program were compared with the scores on these scales of the nonstudy participants in the program who had met the initial screening criteria for the study to assess possible biasing effects from the more intense assessment protocol on the study participants. As can be seen in table 2, the mean pretreatment and posttreatment scores on the total Medical Symptom Checklist, the anxiety items of the Medical Symptom Checklist, the general severity index of the SCL-90-R, and the anxiety subscale of the SCL-90-R for the 22 subjects in the study were comparable to those of the nonstudy participants in the program. The two groups showed statistically significant and equivalent symptom reduction on these measures over the intervention period.

When changes from before to after treatment in anxiety scores and in the number of panic attacks were examined on an individual basis, 20 of the 22 study subjects showed marked improvement (only one patient still had a score over 20 on the Beck Anxiety Inventory after treatment), making it difficult to examine predictors of differential outcome. Consistent with this uniformity of response, no demographic or baseline variables were significantly predictive of outcome. Expectancy ratings also failed to serve as a meaningful predictor of outcome. Self-reported amount of practice (compliance) was also not significantly correlated with any outcome measure. Furthermore, there were no statistically significant differences in outcome between patients with generalized anxiety disorder and those with panic disorder with or without agoraphobia, nor was the diagnosis of major depressive episode associated with outcome.

Adherence to the meditation practices taught in the stress reduction and relaxation program was assessed at 3-month follow-up. In response to the question "Have you been keeping up practice of the stress reduction techniques?" 91% (20 of the 22 subjects) replied in the affirmative, with a relatively homogeneous distribution between single meditation techniques and combinations of methods. Eighty-four percent ($N=16$) of the 19 who responded to this item were practicing formally three or more times per week; 42% ($N=8$) were practicing for 45 minutes or more at a time, 16% ($N=3$) for between 30 and 45 minutes at a time, and 37% ($N=7$) for between 15 and 30 minutes at a time. Twenty-one subjects reported continued use of mindfulness of breathing (an informal mindfulness practice) in their daily lives, with 77% ($N=17$) using it "often" and 18% ($N=4$) using it "sometimes."

DISCUSSION

The rate of completion of the program among the study subjects was high (22 of 24 subjects, or 92%), consistent with previous studies of the stress reduction and relaxation program (18). Twenty of 22 subjects showed marked improvement in both anxiety and depression after the intervention. This improvement was maintained at 3-month follow-up. Improvement was observed both in patients' self-ratings (Beck anxiety and depression scales) and in interviewers' ratings (Hamilton anxiety and depression scales).

Of considerable importance is the statistically significant reduction from pretreatment assessment to post-treatment assessment in the number of subjects reporting one or more panic attacks, an improvement that was maintained at follow-up. There was a statistically nonsignificant tendency for the Hamilton panic scores to decrease between pretreatment and follow-up, suggesting that for the subjects who continued to have panic attacks during and after the intervention, the severity of those attacks declined.

Fear survey and mobility inventory scores also improved significantly, but these changes began during the pretreatment period, suggesting both an effect of the general expectancy of participation and an effect of the exposure to a therapeutic milieu during the evaluation visits.

The uniformly positive response to treatment among the subjects in this small study precluded a successful analysis of predictors of outcome. Compliance was also uniformly reported as moderate to high, indicative of the subjects' positive response to the intervention approach and the successful adoption of a range of new behaviors, including both formal and informal meditation practice.

A major strength of this study was the careful diagnostic assessment procedure we used to obtain *DSM-III-R* diagnoses. Previous studies investigated the use of meditation with normal populations or populations identified by using only nondiagnostic criteria. Such studies may therefore have included patients who would not have met the *DSM-III-R* criteria for generalized anxiety disorder or panic disorders. The results of this study, which focused specifically on patients with generalized anxiety disorder or panic with or without agoraphobia, suggest that mindfulness meditation used in a group format may be a useful treatment approach for these diagnostic groups.

It is also clear that the improvements in panic and anxiety which we observed cannot be attributed solely to participation in the study itself. This is established by the comparison showing that the subjects who participated in the study and the patients in the stress reduction program who met the screening criteria but were not subjected to the intensive research protocol achieved similar reductions in anxiety scores on the SCL-90-R and the Medical Symptom Checklist. This comparison also demonstrates that the results obtained with the study subjects are very likely generalizable to

TABLE 2. Pretreatment and Posttreatment Scores of Patients With Anxiety Disorders in a Study of a Meditation-Based Stress Reduction Program Compared With Scores of Nonstudy Participants in the Program Who Met Initial Screening Criteria for the Study^a

Measure	Study Participants in Program			Nonstudy Participants in Program		
	N	Mean	SD	N	Mean	SD
Medical Symptom Checklist	21			99		
Total score						
Pretreatment		32.05	13.33		30.97	11.55
Posttreatment		23.10	17.75		19.59	12.66
Anxiety score ^b						
Pretreatment		16.95	0.51		15.96	4.67
Posttreatment		11.10	8.50		10.17	5.53
SCL-90-R	20			97		
General severity index score						
Pretreatment		1.08	0.73		1.03	0.56
Posttreatment		0.60	0.54		0.62	0.45
Anxiety subscale score						
Pretreatment		1.56	1.08		1.27	0.79
Posttreatment		0.69	0.68		0.70	0.62

^aAll within-group differences between pretreatment and posttreatment scores were significant ($p < 0.05$) in the two-tailed paired *t* tests. None of the pretreatment scores differed significantly between study participants and nonstudy participants in the unpaired *t* tests, except on the anxiety subscale of the SCL-90-R, for which $p = 0.05$.

^bMean number of symptoms out of the 37 identified as characteristic of patients with anxiety disorders.

the much larger group of patients who met the initial criteria for the study.

The strong reductions in panic symptoms and frequency of panic attacks observed in this study are consistent with the cognitive model of panic (30) and with clinical outcomes from studies of panic disorder in which well-established cognitive (31) and cognitive-behavioral (32) intervention approaches were used. The meditative approach used in the stress reduction and relaxation program shares some attributes with both cognitive and behavioral therapeutic approaches used to treat anxiety and panic. It also differs structurally and theoretically from them in a number of noteworthy respects, as has been noted in a different context by others (33, 34).

In particular, the meditative, cognitive, and cognitive-behavioral approaches share an emphasis on noting sensations and thoughts without viewing them as catastrophic and the use of stress-inducing situations as cues to engage in new behaviors. They also have in common the use of homework assignments to reinforce what was learned in the group sessions. However, the stress reduction and relaxation program differs from cognitive and cognitive-behavioral models in the following important respects.

1. Emphasis is not placed on distinguishing thoughts as positive, negative, or faulty, as in cognitive therapy. Rather, the emphasis is on identifying thoughts as "just" thoughts and acknowledging the potential inaccuracy and limits of all thought, not just thoughts that produce anxiety. This attitude is cultivated in the peri-

ods of formal meditation practice, as well as in informal mindfulness practiced in the course of daily activity.

2. The formal meditation is taught as a daily discipline to be practiced regularly, independent of one's state of anxiety. The emphasis is on meditation as a way of being, as a way of living one's life, and as a way to develop alternative "generic" strategies for coping with stress and pain, rather than as a technique for coping with a specific problem such as panic.

3. The intervention takes place in a nonpsychiatric medical setting with a heterogeneous group of patients who have a wide range of medical and psychological problems. This is a significant departure from the model of cognitive-behavioral therapy, which is typically provided to individuals or groups of patients with a single disorder. Moreover, the focus of the intervention is on the meditation practice itself rather than on a specific disorder or diagnosis or constellation of symptoms.

4. Unlike Barlow's cognitive-behavioral approach, in which subjects are systematically exposed through specific induction exercises to feared internal sensations associated with panic, such as cardiovascular symptoms, hyperventilation, dizziness, and chest muscle tightness (35), there is no attempt at systematic desensitization through the induction of symptoms of any kind during the stress reduction and relaxation program. Although stressful or anxiety-related symptoms are not intentionally evoked, when these experiences arise, either during formal meditation or in the course of daily living, patients are encouraged to see them as opportunities to engage in mindful coping strategies as an alternative to more habitual patterns of emotional reactivity. In this respect, the program utilizes a cognitive restructuring that overlaps with other cognitive and cognitive-behavioral approaches.

5. The observational skills cultivated through mindfulness training differ substantially from those developed by behavioral monitoring techniques. Participants in the program are trained initially to develop concentration (one-pointed attention) through systematic and continued focusing on a restricted field of observation such as breathing or proprioception. Concentration lends stability to one's capacity to observe fearful thoughts and feelings in a nonreactive way. Coupled with mindfulness, concentration gives rise to a nondiscursive, nonanalytical, direct experiencing of the object of attention. This is in contrast to the external data gathering involved in behavioral analysis of antecedents and consequences.

Patients who are able to identify anxious thoughts as *thoughts*, rather than as "reality," report that this alone helps reduce their anxiety and increases their ability to encounter anxiety-producing situations more effectively. The insight that one is not one's thoughts means that one has a potential range of responses to a given thought if one is able to identify it as such. This increased range of options is associated with a feeling of control. It might be hypothesized that this is a feature of a cognitive pathway explaining the clinical observations in this study.

With regard to treatment validation, it should be noted that the duration of meditation practice in the weekly classes becomes incrementally longer over the course of the intervention. By the eighth week, most patients sit in silence in class, with little overt movement for periods of up to 45 minutes. This is a profound behavior change for most patients with panic disorder or anxiety. Such extended periods of stillness serve as an observable behavioral indicator of an individual's increasing ability to concentrate and achieve a degree of calmness over the intervention period. The all-day silent intensive session in the sixth week of the program, involving over 150 patients in one large room, is also an empirical indicator of the development of new behavior. It can be a substantial challenge for patients with panic disorder to sit still for long periods of time, attempting to observe anxious thoughts and impulses as they arise and working with them mindfully rather than succumbing to impulses of reactivity and panic.

A salient limitation of this pilot study is that it did not have a randomly selected comparison group. It also lacked a control for concomitant treatment. However, the group of patients receiving medication showed symptom reduction equivalent to that of the group not receiving any medication, a finding which suggests that the mindfulness approach may be equally useful for patients who receive pharmacotherapy and those who do not. As in treatment studies comparing imipramine and alprazolam (36, 37) and a study of nonpharmacological therapies (6), patients with generalized anxiety disorder and patients with panic disorder responded equally well to the program intervention. However, the number of patients in these two diagnostic categories was small, and a larger, randomized study would be required to determine whether the stress reduction and relaxation program is equally effective in each case or in the case of patients who are receiving pharmacotherapy compared with those who are not. A larger randomized study would also be valuable for comparing the mindfulness-based intervention with other cognitive and cognitive-behavioral therapies.

We observed parallel changes in anxiety and depression scale scores after the meditation program that were similar to those noted by Borkovec et al. (5). However, the presence of comorbid depression in eight subjects in our study was not associated with a statistically significant difference in outcome, as was previously reported (38). This result could mean that the intervention was helpful in alleviating depressive as well as anxiety symptoms. Alternatively, it could have been an artifact of the small size of the study group.

In summary, this pilot study of the efficacy of training in mindfulness meditation in the context of a group stress reduction clinic for medical outpatients showed statistically and clinically significant reductions in symptoms of anxiety and depression in patients with the three core anxiety disorders (generalized anxiety disorder, panic disorder, and panic disorder with agoraphobia) diagnosed according to the *DSM-III-R* criteria. These changes appeared to be independent of par-

ticipation in the research protocol and were maintained at 3-month follow-up.

ADDENDUM

A recently completed long-term follow-up conducted with 18 of the 22 subjects in this study found that after 3 years, the 3-month follow-up levels of anxiety and depression reported here had been maintained.

Brief Treatment of Emergency Room Patients With Panic Attacks

Richard P. Swinson, M.D., Christos Soulios, M.D.,
Brian J. Cox, M.A., and Klaus Kuch, M.D.

Objective: Most research on treatment for panic disorder has involved chronic forms of the illness. To determine the efficacy of early intervention, the authors examined the effects of treatment for patients with panic attacks who were seen in the emergency room, which is the first point of contact with the health delivery system for many persons with panic attacks. **Method:** The subjects were 33 patients with panic attacks seen in two emergency rooms. The presence of panic attacks was confirmed with a modified version of the Structured Clinical Interview for DSM-III-R; approximately 40% of the patients met the DSM-III-R criteria for panic disorder with agoraphobia. The patients were randomly assigned to groups receiving reassurance (N=16) or exposure instruction (N=17). Scores on the Fear Questionnaire agoraphobia subscale, Mobility Inventory, and Beck Depression Inventory and the frequency of panic attacks were determined at baseline, 3 months, and 6 months. **Results:** The subjects who received exposure instruction significantly improved over the 6-month period on depression, avoidance, and panic frequency. The reassurance subjects did not improve on any measure and eventually reported more agoraphobic avoidance. **Conclusions:** These results suggest that early intervention with exposure instruction may reduce the long-term consequences of panic attacks. The exposure instruction was of value even though the subjects had relatively low levels of avoidance at the outset of the study.

(Am J Psychiatry 1992; 149:944-946)

Panic disorder is common in the general population (1), and individuals with panic attacks are frequent users of health services (2). Although much has been written about pharmacological and behavioral treatments for panic-related disorders (3, 4), and there is evidence of a decline in the utilization of health care services by successfully treated agoraphobic patients (5), most of the available literature relates to the treatment of relatively chronic forms of panic disorder. For example, the average length of illness of patients studied in phase I of the Cross-National Collaborative Panic Study (6) was 8 years. Because the emergency room is the first point of contact with the health delivery system for many persons with panic attacks, we examined the effects of

treatment for emergency room patients with panic attacks to determine the efficacy of early intervention.

METHOD

Subjects

Forty patients (23 men, 17 women) in the emergency rooms of two large Toronto hospitals volunteered to undergo the initial assessment interview. Of these 40 patients, 33 (20 men, 13 women) agreed to random assignment to treatment and to follow-up. The age range of these subjects was 19-58 years (mean=31.5 years), and there were no significant differences in demographic variables between the two treatment groups. The Ontario Health Insurance Plan provides no-cost medical services, including emergency room visits, to all residents of Ontario, so access to emergency and ongoing medical care is affected little by financial status.

Procedure

Physicians working in the emergency room were aware of the nature of panic disorder and its somatic

presentation because of ongoing research on hyperventilation in the emergency room. Panic patients were seen by the attending emergency room physician, who excluded the presence of actual physical disease. These patients were then informed of the study by emergency room staff and, if they consented, were contacted within 24 hours by one of us (C.S.). The patients were seen before they left the emergency room or were interviewed within 2 days of their initial emergency room contacts.

At the first interview the patient was assessed with a modified version of the Structured Clinical Interview for DSM-III-R (7) to confirm the presence of panic attacks and rule out other psychiatric disorders. Approximately 40% of the patients met the DSM-III-R criteria for panic disorder with agoraphobia. In almost all cases the patients were just beginning to experience panic attacks and did not have long histories of panic. All subjects were informed of the voluntary nature of the study and signed consent statements.

Before the treatment sessions, phobic avoidance and fear were assessed with the agoraphobia subscale of the Fear Questionnaire (8) and the Mobility Inventory (9). Depressed mood was assessed with the Beck Depression Inventory (10), and panic attacks were assessed by a patient-therapist consensual agreement similar to the procedure used in the Cross-National Collaborative Panic Study (6). The patients completed the self-report measures and panic diaries at baseline, 3 months, and 6 months. One of us (C.S.) interviewed all subjects. This author was not blind to the treatment conditions, and to reduce expectation bias we used only self-report measures.

After the initial interview each subject was assigned, by predetermined randomization, to a reassurance group (N=16) or an exposure instruction group (N=17). Each subject was reassured that what he or she had

experienced was a panic attack and that there was no physical or psychiatric disorder. The exposure instruction group was given additional information beyond that given to the reassurance group. Each subject who received exposure instruction was told that the most effective way to reduce the fear was to confront the situation in which the attack had occurred. The subject was advised to return to this situation as soon as practicable after the interview and to wait there until the anxiety decreased. All sessions were individual, no treatment goals were set, and there was no ongoing contact with the initial interviewer. Each session lasted approximately 60 minutes. The self-report measures were mailed to the subjects a week before the 3-month and 6-month follow-up visits.

RESULTS

A 2x3 (Treatment by Time) mixed factorial multivariate analysis of variance was conducted for each of the dependent variables with Greenhouse-Geisser corrected degrees of freedom. There were significant Treatment by Time interactions on the agoraphobia subscale of the Fear Questionnaire ($F=9.40$, $df=1, 30$, $p<0.001$), on the Mobility Inventory ($F=8.64$, $df=1, 31$, $p<0.001$), and on the measure of panic frequency ($F=3.59$, $df=1, 31$, $p<0.04$). On the Beck Depression Inventory, the Treatment by Time interaction approached statistical significance ($F=3.04$, $df=1, 31$, $p=0.06$).

The results of the post hoc analyses of the scores of the two groups at baseline, 3 months, and 6 months are presented in table 1. There were no significant differences between the two groups at baseline on any measure. The level of phobic avoidance, as measured by the Fear Questionnaire agoraphobia subscale and the Mobility Inventory, was somewhat low at baseline for both

groups. This was not unexpected since the selection of subjects was based on the experience of panic attacks and not the diagnostic criteria for panic disorder or agoraphobia. The exposure instruction group scored significantly lower than the reassurance group on the Beck Depression Inventory at midpoint and endpoint. The frequency of panic attacks in the previous week decreased from 2.53 to 0.76 in the exposure instruction group and increased from 2.50 to 3.38 in the reassurance group. The endpoint difference approached statistical significance.

The exposure and reassurance groups were each examined for changes in scores over time. The exposure instruction group significantly improved on all measures over time—Beck Depression Inventory: $F=7.78$, $df=1, 31$, $p<0.002$; Mobility Inventory: $F=8.56$, $df=1, 31$, $p<0.002$; Fear Questionnaire agoraphobia subscale: $F=6.65$, $df=1, 30$, $p<0.003$; panic frequency: $F=4.13$, $df=1, 31$, $p<0.03$). The reassurance group did not significantly improve on any measure over time. In fact, they became significantly more agoraphobic as shown by their scores on the Fear Questionnaire agoraphobia subscale ($F=3.18$, $df=1, 30$, $p<0.05$).

DISCUSSION

Little is known of the natural history of panic disorder with agoraphobia or the effects of early intervention. The results of this study, for a small group of patients, suggest that early intervention with exposure instructions in a setting that is often the first contact point for health care delivery may reduce the long-term consequences of panic attacks. It is noteworthy that exposure instructions were of value even though the standard measures of agoraphobia revealed relatively low levels of avoidance at the outset. The results also

suggest that reassurance is insufficient to reduce the catastrophic misinterpretation of panic symptoms. These patients became significantly more agoraphobic over the 6-month follow-up period, and this progression may represent the natural course of panic attacks and agoraphobia.

While the present results await replication, we suggest that all patients seeking treatment for panic attacks be given exposure instructions as part of their early assessment or treatment.

Onset of Obsessive-Compulsive Disorder in Pregnancy

Fugen Neziroglu, Ph.D., Richard Anemone, M.A., and Jose A. Yaryura-Tobias, M.D.

Objective: Although the role of pregnancy and childbirth in postpartum psychosis and depression has been studied, the association between pregnancy and obsessive-compulsive disorder has not been specifically addressed. The authors evaluated the role of pregnancy in the onset of obsessive-compulsive disorder. **Method:** Female patients with obsessive-compulsive disorder (N=106) completed a questionnaire assessing age at onset of symptoms, marital status, number of children, age at each pregnancy, and life events associated with the onset of obsessive-compulsive disorder. **Results:** Of the 106 women, 42 were childless and 59 had at least one child each; five others were also childless but had had abortions (N=4) or a miscarriage (N=1). Of the 42 women without children, 12 (28.6%) had first experienced obsessive-compulsive symptoms between the ages of 13 and 15 years, but there were two peaks of onset for the women with children: ages 22–24 and 29–32 years. Of the 59 patients with children, 23 (39.0%) had experienced symptom onset during pregnancy; this was the first pregnancy for 12, the second pregnancy for eight, and the third pregnancy for three. Four of the five women who had had abortions or a miscarriage had experienced the onset or an exacerbation of obsessive-compulsive symptoms during pregnancy. **Conclusions:** The association between pregnancy and the onset of obsessive-compulsive symptoms in these female patients highlights the need for further research on psychological and biological factors associated with pregnancy and obsessive-compulsive disorder.

(Am J Psychiatry 1992; 149:947–950)

The role of biological and psychological factors in the onset of psychiatric symptoms needs further exploration. In particular, the role of pregnancy in obsessive-compulsive disorder deserves empirical assessment. During interviews and treatment of over 500 patients with obsessive-compulsive disorder by two of us (F.N., J.A.Y.-T.), it was observed that the onset of obsessive-compulsive disorder for many women appeared to be during pregnancy.

A review of the literature indicated an abundance of works on the role of pregnancy and childbirth in postpartum psychosis (1–4) and depression (5–10) but only a handful of articles on the relationship between life events, in particular pregnancy, and onset of obsessive-compulsive disorder. Through information provided by psychiatrists, social workers, and self-report, Pollitt (11) found that pregnancy and childbirth were associ-

ated with the onset of obsessive-compulsive disorder in 11% of inpatients and outpatients with obsessive-compulsive disorder. The diagnoses of obsessional illness in the outpatients had been made by one private practitioner, and the inpatients had been diagnosed by many different practitioners, so the reliability of the diagnoses is questionable. Ingram (12), in reviewing detailed case records and personally interviewing and diagnosing hospital patients with obsessional states, noted that for 16.9% of the total patient group the onset had occurred in association with pregnancy, but Lo (13) reported such an association in only 5% of patients. In two case histories (5, 14) obsessive-compulsive symptoms were exacerbated either during pregnancy or during the puerperal period. In addition, the onset of obsessive-compulsive disorder has been associated with viewing or feeling guilty about having repeated abortions (15, 16). The authors of a recent report (17) mailed a questionnaire to 180 consecutively evaluated obsessive-compulsive disorder patients in their database, and 27 (69%) of the 39 female patients described a relationship between the onset or an exacerbation of obsessive-compulsive disorder and some aspect of pregnancy, birth, or care of their children. The wide range of percentages reported in the studies described may be accounted for by the different methods of data collection, the lack of uniform diagnostic criteria, and different patient populations with varying degrees of severity.

Presented at the 145th annual meeting of the American Psychiatric Association, Washington, D.C., May 2–7, 1992. Received June 11, 1991; revision received Sept. 25, 1991; accepted Dec. 5, 1991. ^aNo children from other pregnancies.^bActual age.

None of these studies specifically investigated the onset of obsessive-compulsive disorder during the gestation period. While causality is not implied, on the basis of clinical observation we believe that pregnancy is an important life event that may hasten the onset of obsessive-compulsive disorder. The purpose of this study was to investigate the onset of symptoms during gestation.

METHOD

The participants in this study were 106 female patients who had been diagnosed as having obsessive-compulsive disorder according to *DSM-III-R*. Each patient was first diagnosed by a psychiatrist or licensed psychologist during an initial consultation visit. Later an independent diagnosis was made by the patient's assigned therapist, who was a psychiatrist, psychologist, or assistant psychologist. Finally, the case was presented at an interdisciplinary conference. All patients were seen over 4 years at a private research and treatment center that serves people from all social strata. The facility specializes in the treatment of obsessive-compulsive disorder and served more than 500 female patients between 1979 and 1990. Of the 106 female patients, 42 did not have any children and 59 had at least one child each. In addition, four other childless patients had had abortions and one had had a miscarriage; all of these events occurred during the first trimester. The age characteristics of the patients are given in table 1.

To examine the relationship between obsessive-compulsive disorder and pregnancy, the responses of the 106

FIGURE 1. Age at Onset of Obsessive-Compulsive Disorder for Women With (N=59) and Without (N=42) Children

female patients to a set of questions were recorded on a questionnaire developed for this purpose (available on request). The questionnaire assessed age at onset, marital status, number of children, ages at first, second, third, and other pregnancies, and life events associated with onset of obsessive-compulsive symptoms.

The information obtained from the questionnaire and the patients' verbal reports, psychosocial histories, and progress notes were used as the basis of further inquiries about the onset of obsessive-compulsive disorder symptoms during gestation.

RESULTS

As seen in figure 1, the most common age at onset of obsessive-compulsive disorder for women without children was between 13 and 15 years (mode=14 years). Of the 42 women without children, 28.6% (N=12) experienced onset during this period. On the other hand, there were two peaks for the 59 women with children. Because of the bimodal nature of this distribution, it was important to look at the modal ages rather than the mean ages. The first peak appeared at ages 22–24 years, during which 18.6% (N=11) of the women with children experienced onset, and the second peak was between ages 29 and 32 years, during which 25.4% of the women (N=15) first experienced obsessive-compulsive disorder. The mean, median, and modal ages at onset are shown in table 1.

Of the 59 women who had children, 31 (52.5%) were pregnant for the first time between the ages of 22 and 26; of the 37 who had a second pregnancy, 10 (27.0%) were between 23 and 25 and 10 (27.0%) were between 29 and 30; and of the 15 who had a third pregnancy, eight (53.3%) were between the ages of 30 and 33.

Of the 59 patients who had children, only one (1.7%) indicated a decrease of symptoms during the gestation period, whereas 23 (39.0%) each had an onset of illness during gestation. Of these 23 patients, 12

(52.2%) experienced onset with the first child, eight (34.8%) with the second child, and three (13.0%) with the third child. In addition, of the five patients who had abortions or a miscarriage, three experienced the onset of obsessive-compulsive disorder during the time they were pregnant and one had an exacerbation of symptoms. As soon as the pregnancy was aborted, the symptoms disappeared. If the three patients in this group are added to the other women who experienced symptom onset during pregnancy, the percentage of women with onset during this time would rise from 39.0% to 40.6%.

As shown in table 2, 44 patients could not recall any life event that was associated with the onset of obsessive-compulsive symptoms. For many it was a sudden, unexpected occurrence. However, of the life events that were perceived as being important, pregnancy more than any other life event was associated with the onset of obsessive-compulsive disorder. Physical illness was reported to be an important life event during this period by 8.5% of the women without children, and previous panic disorder was reported by 8.5% of the women with children. Other life events that were associated with the onset of obsessive-compulsive disorder by women without children were the death of a loved one, moving, and marital/family stress (4.3% in each case). Three women who did not have children but had had abortions noted that the onset of their obsessive-compulsive symptoms occurred while they were pregnant. After the abortion, which took place in the first trimester, the symptoms disappeared, and years later obsessive-compulsive symptoms appeared again without an associated life event.

DISCUSSION

Certain life events, such as pregnancy, seem to precipitate psychiatric disorders (9). The results of this study indicate that a large percentage (39.0%) of the women with obsessive-compulsive disorder who had children developed the disorder during pregnancy.

Other life events that appeared to be important were previous panic attacks and previous physical illness. The frequency of women who did not associate a particular life event with the onset of their obsessive-compulsive disorder was higher among the women who were childless (55.3%) than among the women who had children (30.5%). This may be partially explained by the fact that many women with children attributed their symptoms to pregnancy, whereas the women without children in general developed obsessive-compulsive disorder at an earlier age and therefore may have been unable to recall any associated major life event.

It is possible that the patients with children and those without children had different developmental histories of obsessive-compulsive disorder. According to figure 1, the patients without children appeared to have a peak onset during puberty and those with children had

^aIncludes the five women who had had abortions or a miscarriage.

peaks around the times of their pregnancies, ages 22–24 and 29–32 years. Perhaps the early development of obsessive-compulsive disorder influenced the group without children to remain childless. Many patients commented that they could not entertain the possibility of raising children while being chronically ill.

Childbirth and pregnancy can be stressful. After our study 10 women with children and 10 without were asked about the reasons they chose or did not choose to have children, their levels of stress before, during, and after pregnancy, and their stress levels at pregnancy in comparison with those at other stressful times in their lives. It appears that the women who chose to have children did not view pregnancy as one of the more stressful times in their lives. In fact, they reported being happy during pregnancy. The only stress appeared to be the presence of symptoms of obsessive-compulsive disorder. Those who were childless indicated they did not want children because of the chronicity of their illness and their perceived inability to raise a child and cope with their obsessive-compulsive symptoms at the same time. Of course, the information on stress was all collected retrospectively and the validity of the responses of these women may be questioned.

These initial data suggest that pregnancy may be an important precipitating factor in the onset of obsessive-compulsive disorder. Further research needs to be conducted on risk factors, biological vulnerability, and, if possible, preventive measures that can be taken during early pregnancy.

New Policy Regarding Letters to the Editor

Effective immediately, Letters to the Editor critical of an article published in the *Journal* must be received within 6 weeks of the article's publication; Letters from outside the United States must be received within 12 weeks. Letters received after the deadline will not be considered and will be returned unreviewed.

Psychiatry and the Homeless Mentally Ill: A Reply to Dr. Lamb

Douglas Mossman, M.D., and Michael L. Perlin, J.D.

Homeless mentally ill persons are highly visible subjects of ongoing public discussion and potent symbols of a host of contemporary social problems. They present psychiatry with a scientific challenge that calls for further elucidation of the sources of their mental illness and for fashioning possible solutions to their problems. They also present a moral challenge that requires psychiatrists to acknowledge the cultural, political, legal, and economic context of the mental problems of the homeless in the course of deciding what should be done to help them. H. Richard Lamb has proposed a program of aggressive outreach and psychiatric hospitalization for the homeless mentally ill. The authors believe that his proposal misconstrues the problems and needs of homeless mentally ill individuals; it would also needlessly infringe upon their freedom, further stigmatize them, and probably not help them. The authors offer an alternative understanding of the plight of the homeless mentally ill which places their problems within a larger context of social trends and domestic issues that society has been reluctant to confront. Psychiatrists can help the homeless mentally ill by championing their liberty rights and by focusing public discourse on the broad national need for improved access to medical and psychiatric care.

(Am J Psychiatry 1992; 149:951-957)

Although mentally ill persons constitute only a minority of the total homeless population (1), they are highly visible subjects of ongoing public discussion and potent symbols of a host of contemporary social problems (2, sections 7.23-7.25). To many observers, the homeless mentally ill are vivid testimony to governmental indifference to the plight of poor citizens; they represent our nation's failure to respond compassionately to its people's needs for shelter, sustenance, and effective medical care. To others, the homeless are a loathsome, monolithic population of crimi-

nals and mentally ill souls negligently released from jails and hospitals, unable to care for themselves, and potentially dangerous to the community (3, 4); they are seen as evidence of public-sector psychiatry's misguided policies and of irresponsible legal advocacy on behalf of hospitalized patients. Former New York City mayor Ed Koch has characterized the last three decades' effort toward deinstitutionalization as one of the "lunacies of government" and regards libertarian attorneys who advocate for patients' rights as "crazies" (5, 6). More sober analyses recognize that deinstitutionalization has not caused homelessness and that the inadequacies of deinstitutionalization stem not so much from the idea itself as from its misexecution over the past two decades, from lack of public consensus about policies for dealing with former hospital patients, and from public mental health systems' failure to offer comprehensive outpatient treatment that could help indigent persons with severe mental illnesses to live in the community (7-9).

Received Feb. 19, 1991; revisions received Aug. 5 and Nov. 20, 1991; accepted Dec. 12, 1991. From the Department of Psychiatry, University of Cincinnati College of Medicine; the Psychiatry Service, Department of Veterans Affairs Medical Center, Cincinnati; and New York Law School, New York City. Address reprint requests to Dr. Mossman, Psychiatry Service (116A), Department of Veterans Affairs Medical Center, 3200 Vine St., Cincinnati, OH 45220.

The authors thank Debbie Dorfman and Cynthia Dokas for research assistance.

The homeless mentally ill present psychiatry with a twofold challenge. One challenge is scientific, calling on psychiatrists to elucidate the sources of mental illness among the homeless and to describe potential solutions to their emotional problems; this challenge asks psychiatrists what *can* be done to help homeless individuals who are mentally ill. The other challenge is moral, requiring psychiatrists to acknowledge the cultural, economic, legal, and political context of homelessness as it affects judgments about medical issues; this challenge asks psychiatrists to choose, from among many possible courses of action, what they *should* do to help the homeless mentally ill.

In a Commentary published in the *Journal* (10), H. Richard Lamb, M.D., exhorted psychiatrists to "save the homeless mentally ill" through treatment programs combining aggressive community outreach, civil commitment, and involuntary pharmacotherapy. Dr. Lamb was coauthor of the APA task force's recommendations concerning the homeless mentally ill (7). His proposals thus constitute an important conceptualization of this population's problems and of public psychiatry's optimal response. From both a scientific and a moral standpoint, however, we find this conceptualization unsatisfactory. In this Reply, we offer a contrasting conceptualization of the problems of the homeless mentally ill and suggest to psychiatrists what we believe is a more defensible, if more modest, response to these problems.

THE HOMELESS MENTALLY ILL IN SOCIAL CONTEXT

The homeless mentally ill have many problems, two of which are homelessness and mental illness. Although these are problems that are endured by and interact within individuals, the current state of homeless persons who suffer psychiatric symptoms reflects a confluence of social developments and attitudes about the poor and the mentally ill.

Although homelessness is by no means a new phenomenon, contemporary homelessness follows a decade in which all but the wealthiest Americans have experienced, in constant dollars, net decreases in annual income (11). As one of us has discussed in more detail elsewhere (2, 12), four other social developments have contributed particularly to homelessness.

First, the average age of homeless individuals has declined in the last quarter-century. "Baby boomers" have contributed substantial numbers to our cities' homeless populations, as well as special demographic features: they are more likely to use "recreational" drugs, and they also include Vietnam veterans, who themselves comprise a substantial fraction of the homeless (13).

Second, the last two decades have witnessed substantial losses of low-income housing, reflecting the effects of tax abatement programs that encourage urban "gentrification" (1, 14), limited federal funding for subsidized housing (15), and growth-restricting local housing ordinances (16). This has decreased the potential

availability of housing for the poor in general and of specialized housing for the chronically disabled.

Third, the discontinuation of Supplemental Security Income (SSI) benefits that was initiated by the Reagan administration has had a disproportionate impact on persons with mental disabilities (17). Only a fraction of all homeless persons receive government assistance, and their inflation-adjusted median income has declined by two-thirds over the last three decades (18). Although Congressional and Supreme Court actions have caused a partial reversal of this trend (19, 20), the SSI disability system remains a "flawed" and "incoherent" one (21, pp. 915, 964), and the earlier reduction of benefits remains a significant factor in the increased number of homeless individuals (22-25).

Finally, many of the nondisabled homeless had limited work skills and were chronically unemployed before they became homeless (26). As our changing economy provides fewer well-paying industrial-sector jobs for unskilled or semiskilled workers, ethnic minorities are making up an increasing portion of the homeless population (1).

Recent findings consistently deemphasize the significance of deinstitutionalization as a source of homelessness (27). Although a substantial minority of homeless persons might benefit from some form of psychiatric treatment, only a small minority of the homeless need psychiatric hospitalization (28). Those among the homeless who have histories of psychiatric treatment have social backgrounds and characteristics (such as poverty, poor work skills, and lack of housing and social support) that are similar to those of homeless persons without psychiatric histories. It thus seems clear that mental illness is not the primary cause of the plight of the homeless mentally ill (29-31).

The fact that many homeless persons suffer from untreated psychiatric symptoms must be considered in a larger context which recognizes the vulnerability of millions of Americans who have no medical insurance coverage at all, as well as the various forms of discrimination against psychiatric patients that are characteristic of the American health care system. Lack of private health insurance coverage is associated with poor physical health (32) and with elevated prevalences of major mental illnesses (33). Homelessness is, if nothing else, a condition of poverty (34-36), and poor individuals in general are at increased risk for episodes of psychiatric illness (37).

CRITIQUE OF DR. LAMB'S VIEW

Although Dr. Lamb has elsewhere recognized that "homelessness among the chronically and severely mentally ill is symptomatic of the grave problems facing them generally in this country" (38, p. 498), the demographic factors, economic trends, government policies, and social attitudes that contribute to homelessness among the mentally ill received scant attention in his Commentary (10). Dr. Lamb instead offered an indi-

vidually and biologically focused view of their situation and conceptualized their problems in a manner that seems, to use George Engel's terminology (39), strikingly "biomedical."

"A large proportion of the homeless mentally ill," Dr. Lamb wrote, "tend to be resistant to taking psychotropic medications, to treatment generally, and to accepting any living situation." They often lack living situations because they are "too paranoid" or have "disabling functional deficits . . . [that] include disorganized thinking and actions, poor problem-solving skills, and an inability to mobilize themselves due to depression" (10, p. 650). Thus "the great majority" of homeless mentally ill persons need "structure in terms of a controlled living situation" where their taking psychotropic medications can be assured and where "they are given as much freedom as they can handle but not more. For many, this will mean a locked setting" (10, p. 651).

Although he has elsewhere criticized recommendations for massive rehospitalization (40), Dr. Lamb asserted that "outreach teams including psychiatrists should bring all" incompetent homeless persons "to hospitals, involuntarily if need be" (10, p. 650). If the funds necessary for providing high-quality hospital care "are not available, it is more humane to place these patients in [substandard] hospitals . . . than to leave these neglected human beings on the streets" (10, p. 651).

While the efficacy of medication in preventing symptom relapse and rehospitalization of many mentally ill individuals is quite familiar to physicians, so are the limitations of pharmacotherapy, particularly for schizophrenia. A substantial fraction of patients respond poorly to psychotropic medication or relapse while taking maintenance medication (41, 42). Moreover, the long-term outcome for most patients with chronic thought disorders is often characterized by lifelong disability (43, 44). Dr. Lamb's hope that more involuntary pharmacotherapy will substantially alter the lives of the homeless mentally ill ignored these well-established findings.

Dr. Lamb also ignored the attitudes of former public hospital patients toward their involuntary treatment. Although he cited reports suggesting that patients often view their commitment positively, other reports present a contrasting view: refusal of treatment also may reflect a person's knowledge of, or legitimate fears about, the quality of treatment rendered in state hospitals (45-47). A subgroup of the homeless mentally ill shun the public mental health system; they prefer living on the streets to living in institutions and prefer to live with symptoms of mental illness rather than suffer the side effects of medication in state hospital settings (48-50). Some psychiatrists may regard such judgments as evidence of mental illness, but the documented record of abysmal conditions in many state hospitals (17, 51) suggests that some of the homeless mentally ill may be making reasonable choices. Many homeless mentally ill persons *will* accept medication in alternative social settings, such as community shelters (52), and *will* seek medical care in general hospitals (53).

We are puzzled that Dr. Lamb thinks the homeless mentally ill would be helped by aggressive efforts toward involuntary hospitalization. He believes that after "brief hospitalization . . . mentally ill individuals can be placed voluntarily in a suitable living situation" and that a well-staffed and "well-functioning system of case management" might enable chronically ill patients to live in the community and receive needed services and treatment "on a voluntary basis" (10, p. 650). However, he does not "think there's any real evidence that the public is willing to pay for it and that it really could be done in the larger cities where the largest numbers of chronically mentally ill are" (28, p. 7). Elsewhere, one of us has questioned the willingness and competence of our public institutions to respond to the problems of the homeless mentally ill (12). Dr. Lamb seems to agree: "Not only are there insufficient funds to do this but the bureaucracies are too ponderous and inefficient . . . to set up a comprehensive and competent case management system" (10, p. 650). Recent empirical reviews and critical analyses suggest that broadening civil commitment standards results in institutional overcrowding and lessened opportunities for treatment of voluntary patients (45, 46). Also, while there is now federal legislation providing funds to selected programs to aid homeless individuals—the McKinney Homeless Act (54)—it is clear that this act will not be a panacea for any substantial number of the nation's homeless (55).

Dr. Lamb has described the widespread suspicion of and intolerance toward persons with serious mental illness (38), which constitutes another obstacle to their integration into the community after hospitalization. Lack of appropriate disposition is the "single most critical factor which prevents effective service coordination and implementation of rational discharge planning" (16, p. 113). Discriminatory zoning litigation (2, section 7.22; 3), the public's opposition to the insanity defense following John Hinckley's trial (56), and persistent media-reinforced misassociations between violence and mental illness (57) provide just a few of many possible examples of society's "limited tolerance of mentally disordered behavior" (38, p. 499). This kind of stigmatization appears especially pernicious in the face of evidence that patients receiving nonhospital treatment consistently do better than those who are institutionalized (58). There are numerous reports of successful, noninstitutional approaches to the treatment of the chronically mentally disabled in which programs and services providing a sufficient level of social support have enabled such individuals to rejoin the community (12, note 186; 59-62).

WHAT SHOULD PSYCHIATRISTS DO?

Our discussion has emphasized that the problems of the homeless mentally ill result from an interaction of their biological and psychological pathology with social conditions about which psychiatrists should be concerned, but which are not amenable to medical in-

interventions alone (63, 64). The Robert Wood Johnson Foundation Program on Chronic Mental Illness is based on the premise that coordination and improved availability of a full range of community services (including social and vocational rehabilitation as well as outpatient psychiatric treatment) are needed if persons with severe psychiatric disorders are to succeed outside of hospitals (65). A key feature of the program is "the expansion of housing options for people with chronic mental illness" (66). Indeed, Goldman et al. believe that "the Department of Housing and Urban Development's contribution of Section 8 housing certificates" was "the single most powerful motivator for cities to participate" in the program (67, p. 1229).

Goldman et al. also noted that "the need for comprehensive services exceeds the resource capacity of most, if not all, of the sites" participating in the Robert Wood Johnson Foundation program (67, p. 1229). We suspect that this holds true for service systems across the nation. We share Dr. Lamb's skepticism about the likelihood that local, state, or federal governments will soon embrace and provide financial support for the comprehensive systems of social support needed to help poor mentally ill patients succeed in the community. However, we reject Dr. Lamb's suggestion that psychiatrists "work within the limits of what society is willing to pay" (10, p. 650) and encourage the involuntary hospitalization of incompetent homeless individuals.

If society is willing to provide funds only for often-abysmal state hospitals that discharge patients right back to the conditions and situations which led to their need for hospitalization, how would more involuntary hospitalization substantially change matters? (45, 46). Dr. Lamb might argue that under such circumstances, psychiatrists still should do something: administer medication plus "structure" (i.e., involuntary hospitalization and other confinements) to ensure that symptoms resulting from "noncompliance" are minimized. Yet the dictum *primum non nocere* requires physicians to ask themselves how a policy of involuntary hospitalization and an endorsement of stigmatizing (and—if Dr. Lamb is right about society's lack of generosity—probably futile) incarcerations would affect both the homeless mentally ill and the homeless in general. We are concerned that Dr. Lamb's recommendations would reinforce common misperceptions that deinstitutionalization has caused homelessness, that all of the homeless are disturbed and incompetent, and that the public mental health system is to blame for, and therefore can "solve," the problem of homelessness—all the while abetting, justifying, and reinforcing society's reluctance to examine the fundamental economic and social questions underlying homelessness.

Appelbaum sagely noted that courts and legislatures have often evinced "the universal human desire for someone else to make the hard decisions" (68, p. 762) in their willingness to let psychiatrists resolve difficult legal issues. Local, state, and federal governments also may be tempted to let psychiatrists provide solutions (e.g., institutionalization) to the complex and embar-

assing problems of the homeless. Society may approve of psychiatric outreach teams' removing the homeless mentally ill to hospitals, but this practice could obscure physicians' traditional allegiance to individual, consenting patients who seek their services. Providing a "clinical" solution—involuntary hospitalization—to the problems of the homeless mentally ill reinforces psychiatrists' role in performing an already onerous "duty": the authorization of preventive detention (69). As Aviram cautioned, "We must be aware of the potential collusion between the state bureaucracy and psychiatry that may be at the expense of the recipients An unbalanced need for treatment-medical model of mental commitment may lead psychiatry into . . . a role of social control agents" (70, p. 175).

Rather than offering simplistic, medical "solutions" for individuals already cursed by especial social prejudice, psychiatrists should redirect public attention toward the manifold social problems that are the important causes of homelessness in general. They can point out that many homeless persons are interested in receiving psychiatric treatment, but they understandably put a higher priority on meeting their basic material needs (71). Psychiatrists can emphasize the APA task force's view that addressing "the problems of the homeless mentally ill must begin with provisions for meeting their basic needs: food, shelter, and clothing" (7, p. 5) and can remind the public that "providing psychiatric services to a mentally ill homeless person leaves the person still homeless, just as providing food to a hungry homeless person leaves the person still homeless" (72, p. 213).

If they are interested in having society view the mentally disabled with respect and if they want their patients and their specialty to be free of the stigma associated with psychiatric practice, psychiatrists should champion a view of mentally ill persons that emphasizes the same liberty rights for them as are assumed for persons with other medical disorders. Adults generally are under no obligation to attend to their medical problems; they can smoke, overeat, fail to exercise, and otherwise neglect their health because they have a fundamental right to be left alone (73, 74). What ethicists have termed an "implicit contract" forms the basis of the doctor-patient relationship; a person's voluntary decision to seek medical help ordinarily permits creation of the treatment relationship (75). It is sad and frustrating when any individual pointlessly suffers significant symptoms that might respond to medical treatment, yet we must accept this as the consequence of conforming medical practice to general social norms concerning the protection of individual freedom and dignity.

Throughout his discussion, Dr. Lamb referred to homeless mentally ill persons who are "resistant" to accepting treatment as "patients." To emphasize the benefits and efficacy of treatment, psychiatrists might better refer to obviously troubled and untreated street people as "nonpatients." This designation indicates that such individuals are not receiving care that could alleviate symptoms but acknowledges their presumed

right to make their own decisions, even if those decisions are not the ones that doctors would recommend.

Increasingly, it is suggested that reinstitutionalization would help solve the problem of the homeless. In responding to this assertion, psychiatrists should keep in mind that "homelessness has become a public policy battleground" (72, p. 212). Although mental health systems and civil libertarians are convenient targets for those who wish to make accusations or assign blame, homelessness is a complex problem for which all citizens ultimately share responsibility. Psychiatrists surely share responsibility for some aspects of the problem of homelessness, and they can demonstrate a constructive public response by acknowledging their profession's failings without being unduly defensive. Psychiatrists can also demonstrate their maturity by resisting the temptation to counterblame attorneys or courts that have affirmed psychiatric patients' rights and by resisting the temptation to provide the whole solution to a problem for which they bear only a small portion of the responsibility.

Psychiatrists also could respond by reminding the public that only a minority of the homeless have severe psychiatric disorders, that only a small fraction of the homeless are incompetent to make decisions about their need for hospitalization, that incompetence is a legal status which judges, not psychiatrists, determine (51, 76), and that, ultimately, homelessness is a problem of poverty and resource distribution. Incompetence and mental illness are, of course, not identical. Psychiatrists should underscore their expertise in the latter and reinforce the role of courts in adjudicating the former. They should emphasize that the nature and duration of the confinement of noncriminals, and the method for determining who among the mentally ill should be deprived of liberty, remain legal issues (77, 78). Doing so would also emphasize psychiatrists' presumption of respect for individuals' decision-making power and their endorsement of the same contractual model of treatment that is presumed for nonpsychiatric conditions.

Finally, psychiatrists can join Peele (79) in championing private office practice as the preferred locus of psychiatric care, including care of individuals whose treatment traditionally is relegated to the public sector. The availability of psychiatric outpatient treatment on a par with other office treatment is conducive to the spending of health care dollars on treatment itself (as opposed to institutional custody) and can assure patients' access to the pharmacologic and psychotherapeutic advances that psychiatry has witnessed over the last two decades (79). Psychiatrists in private practice could offer to provide services to homeless persons by setting aside a portion of their time to see persons at shelters or other facilities that serve the homeless. In doing this, careful thought should be devoted to establishing treatment "parameters" so that patients would not be (or feel) coerced into seeing psychiatrists, and psychiatrists would not feel pressured to coerce patients into accepting unwanted forms of treatment. All persons with psychiatric disturbances (including the homeless mentally ill)

should be granted the autonomy typically accorded to persons who seek medical treatment in general, including a contractual relationship with a physician of one's choosing and the rights, privacy, and dignity characteristic of office practice.

CONCLUSIONS

Maimonides offered guidance for those perplexed by the plight of the homeless mentally ill:

Anticipate charity by preventing poverty; assist the reduced fellowman, either by a considerable gift, or a sum of money, or by teaching him a trade, or by putting him in the way of business, so that he may earn an honest livelihood, and not be forced to the dreadful alternative of holding out his hand for charity. This is the highest step and the summit of charity's golden ladder. (*Charity's Eight Degrees*, quoted in 80, p. 74)

Psychiatry's understanding of the central role of self-esteem in emotional life (81) need not be abandoned when we contemplate homelessness and mental illness. In both their care of individuals and their contribution to public discourse, psychiatrists can best serve the liberty rights and the emotional needs of the homeless mentally ill through a *prima facie* affirmation of the legitimacy of their wishes and by helping the general public gain insight into the underlying social problems of which homeless mentally ill persons are vivid and unfortunate victims.

Regulation of Appetite and Cholecystokinin Secretion in Anorexia Nervosa

Thomas D. Geraciotti, Jr., M.D., Rodger A. Liddle, M.D., Margaret Altemus, M.D., Mark A. Demitrack, M.D., and Philip W. Gold, M.D.

Six patients with anorexia nervosa, the same patients after weight normalization, and six healthy control subjects had similar fasting and postprandial plasma cholecystokinin concentrations. These data do not support the hypothesis that low levels of hunger and food intake in anorexic patients reflect hypersecretion of this endogenous hormone, which is thought to inhibit hunger, promote satiety, and reduce feeding.

(Am J Psychiatry 1992; 149:958-961)

Studies in experimental animals (1,2) show that cholecystokinin in both the CNS and periphery promotes satiety during feeding. Studies in human volunteers (3,4) also support a satiety-inducing role for peripherally secreted cholecystokinin. In this regard, we have shown (3) that the secretion of cholecystokinin into plasma during a meal strongly correlates with satiety in healthy volunteers. We also observed (3) abnormally low endogenous cholecystokinin release after eating in bulimic women, and the magnitude of this impairment correlated significantly with impaired postprandial satiety. We postulated that this impairment in meal-related plasma cholecystokinin might reflect an intrinsic defect that predisposed patients with bulimia nervosa to pathological eating behavior or that it might be a consequence of abnormal eating behavior which was perpetuating the illness.

In the present study we sought to determine whether patients with anorexia nervosa have abnormally high plasma cholecystokinin concentrations, which might be contributing to their pathologically restricted eating.

Received March 12, 1991; revision received Nov. 6, 1991; accepted Dec. 12, 1991. We restudied each anorexic patient after correction of her weight loss to explore whether the cholecystokinin response to feeding was related to body weight in our cohort.

METHOD

Subjects

Six female patients with anorexia nervosa were studied, and all six were again studied several months later, 3-4 weeks after restoration of their ideal weights (3). Three of these patients had histories of sporadic binge eating. The control subjects were six age- and sex-matched volunteers in good health and without personal or family histories of eating disorder, affective disorder, alcoholism, or schizophrenia. All normal subjects were within 10% of their ideal body weights (3). All patients and control subjects were medication free and did not smoke. The mean age of both the patients and control subjects was 24 years (SD=5 and SD=4, respectively). The mean duration of anorexia in our patients was 6 years (SD=5). Mean body weight was 37.3 kg (SD=3.5) in the anorexic patients and 56.0 kg (SD=6.2) in the normal subjects. After refeeding, the patients' mean weight increased to 52.6 kg (SD=3). All subjects gave informed, written consent before participating in the study, which was approved by the National Institute of Mental Health Committee on Human Subjects.

Procedure

The subjects adhered to a controlled low-monoamine diet. Each subject was studied in the morning after an overnight fast. Blood samples were drawn through an indwelling 21-gauge intravenous catheter in the antecubital fossa and collected into iced heparinized tubes at various times before and after consumption of the test meal, and they were immediately centrifuged at 4 °C to obtain plasma for cholecystokinin determination.

After the postfast samples were obtained, the subjects were each fed 7 ml/kg of a vanilla-flavored mixed liquid meal. The meal consisted of one egg, half-and-half (milk and cream), and a commercial powdered instant breakfast supplement. The meal contained 1.6 calories/ml and had a macronutrient composition of 40% fat, 20% protein, and 40% carbohydrate. Each subject consumed the entire meal within 2 minutes, except patient 5 during the low-weight phase. This subject consumed only 2 ml/kg of the test meal and adamantly refused more, tearfully complaining of nausea. This patient was thus again given only 2 ml/kg of the test meal during her weight-recovered study. She had no difficulty in consuming this second meal. One matched control subject was also fed 2 ml/kg of the test meal.

Hunger and satiety were assessed with 100-mm visual analogue scales, which included distractors (3).

Cholecystokinin concentrations in plasma were measured by a specific and sensitive bioassay, which has been extensively validated (5). Briefly, cholecystokinin was absorbed onto Sep-Pak cartridges and dried under nitrogen, and cholecystokinin bioactivity was measured with isolated rat pancreatic acini. The minimal detection limit was 0.2 pmol/liter. The recoveries of cholecystokinin-8 and cholecystokinin-33 added to charcoal-stripped plasma were 92% (SD=6%) and 85% (SD=10%), respectively. The intra- and interassay coefficients of variations were 8.6% and 12.7%, respectively.

Statistical Analysis

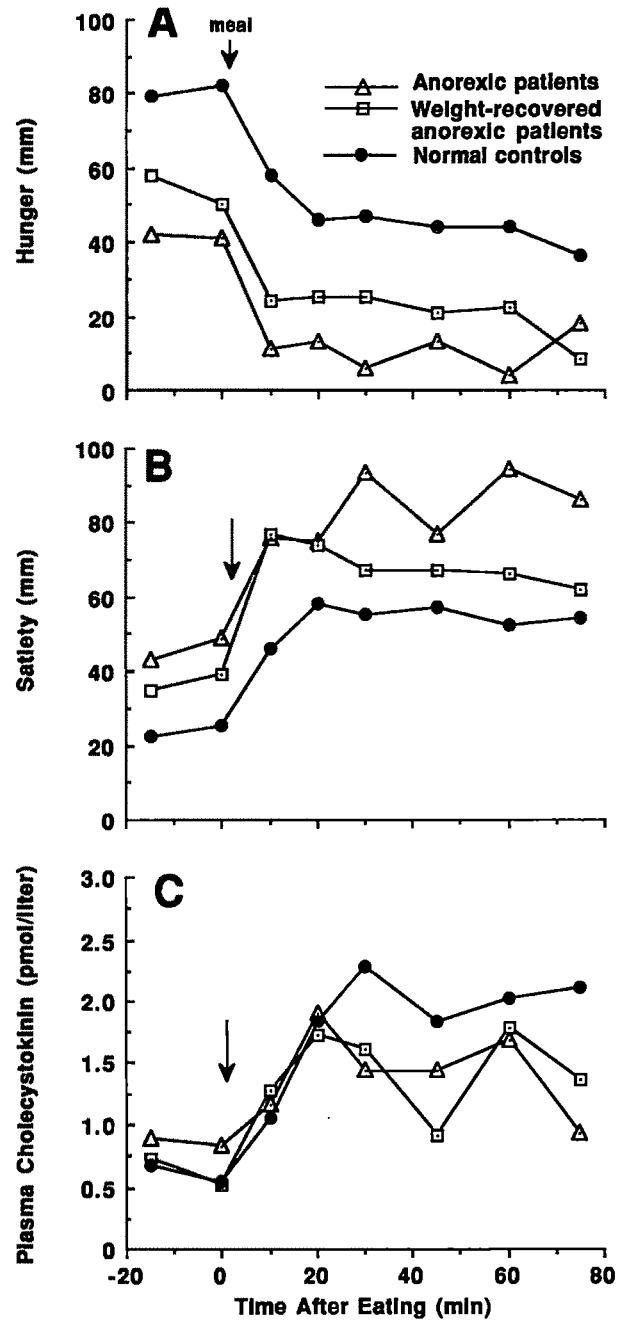

Net cholecystokinin response was calculated as total area under the concentration-time curve, minus the mean basal value multiplied by 75 minutes. Group comparisons were analyzed with the Student's two-tailed *t* test. For longitudinal comparisons of the same patients the two-tailed paired *t* test was used. All values are expressed as the mean and standard deviation of the mean.

RESULTS

Hunger and Satiety Ratings

Ratings of hunger and satiety before and after the test meal are shown in figure 1. We calculated a mean basal rating for each group on the basis of the values at -15 and 0 minutes, and mean postprandial ratings were

FIGURE 1. Fasting and Postprandial Levels of Hunger, Satiety, and Plasma Cholecystokinin in Patients With Anorexia Nervosa Before and After Weight Recovery and in Normal Control Subjects^a

^aThe arrow indicates the beginning of the meal. Hunger and satiety were rated on 100-mm visual analogue scales; cholecystokinin is expressed as cholecystokinin-8 equivalents.

based on all of the values after the beginning of the meal. The mean basal (fasting) hunger sensation, as rated on the 100-mm visual analogue scale, was 43 mm (SD=37) for the underweight patients with anorexia nervosa and 82 mm (SD=13) for the normal control subjects ($t=2.36$, $df=10$, $p<0.05$) (figure 1, part A). After the correction of their weight loss, the mean basal

hunger rating of the anorexic subjects was still somewhat lower than the control value: 49 mm (SD=38) versus 82 mm (SD=13) ($t=1.91$, $df=10$, $p<0.10$). After consumption of the test meal, the mean hunger rating was much lower for the underweight anorexic subjects than for the control subjects—10 mm (SD=16) versus 46 mm (SD=13) ($t=4.2$, $df=10$, $p<0.05$)—but after weight correction the patients' rating of postprandial hunger rose to 23 mm (SD=32), which was not significantly different from control values ($t=1.99$, $df=5$, $p=0.10$) (figure 1, part A). However, the normal subjects, the anorexic patients, and the weight-corrected patients showed similar mean reductions in hunger ratings after the consumption of the test meal: 35 (SD=19), 31 (SD=38), and 26 (SD=38) mm, respectively.

The mean basal satiety ratings were 26 mm (SD=17) for the control subjects, 48 mm (SD=34) for the underweight anorexic patients ($t=1.40$, $df=10$, n.s.), and 39 mm (SD=25) for the anorexic patients after short-term weight normalization ($t=1.02$, $df=10$, n.s.) (figure 1, part B). The mean postprandial satiety ratings were 53 mm (SD=13) for the healthy subjects and 78 mm (SD=35) for the underweight anorexic patients ($t=1.65$, $df=10$, $p=0.13$). After correction of their weight loss, the anorexic patients had a mean postprandial satiety rating of 68 mm (SD=26); the difference from the rating when they were underweight was nearly significant ($t=2.17$, $df=5$, $p=0.08$). The mean postprandial changes in satiety were similar in all subject groups, averaging 27 (SD=23), 31 (SD=44), and 30 (SD=28) in the healthy subjects, underweight anorexic patients, and patients after weight restoration, respectively (figure 1, part B).

Plasma Cholecystokinin

The basal fasting plasma cholecystokinin concentrations were similar in all groups, averaging 0.6 pmol/liter (SD=0.2) in the control subjects, 0.9 pmol/liter (SD=0.8) in the underweight anorexic patients ($t=0.83$, $df=10$, n.s.), and 0.6 pmol/liter (SD=0.3) in the anorexic patients after weight recovery ($t=0.27$, $df=10$, n.s.) (figure 1, part C). Similarly, no significant differences between subject groups in peak postprandial plasma cholecystokinin concentrations were observed. The mean peak levels were 2.9 pmol/liter (SD=1.1) in the healthy subjects, 2.2 pmol/liter (SD=1.4) in the anorexic patients, and 2.3 pmol/liter (SD=1.7) in the anorexic patients after the short-term weight correction (data not shown). Furthermore, the net integrated cholecystokinin responses during test meal administration were similar: 100 pmol/liter-min (SD=52) in the control subjects, 73 pmol/liter-min (SD=67) in the underweight anorexic patients ($t=0.79$, $df=10$, n.s.), and 73 pmol/liter-min (SD=59) in the anorexic patients after weight correction. However, the anorexic group experienced great intraindividual changes in cholecystokinin secretion between the low-weight and weight-corrected conditions. The two patients with the lowest cholecystokinin responses to feeding while at low weight, both of whom had histories of sporadic binge eating, had the highest

responses after weight normalization, and the two patients with the most robust cholecystokinin responses while at low weight, both of whom had pure restricting-type anorexia, had blunted responses after refeeding. One anorexic subject (patient 5) had high fasting plasma cholecystokinin concentrations (averaging 2.5 pmol/liter) while underweight, which fell to 0.5 pmol/liter while fasting after weight normalization.

Glucose and Urinary Ketones

The fasting glucose levels in all subjects were normal, ranging from 71 to 90 mg/dl. No urinary ketones were detectable in any subject, including the low-weight anorexic patients.

DISCUSSION

Like previous investigators (6, 7), we found that patients with anorexia nervosa experienced more satiety and less hunger while fasting and after eating than did normal subjects. These appetite abnormalities were ameliorated by short-term weight correction. At the same time, there were no differences between anorexic patients, the same patients after weight recovery, and healthy control subjects in the mean postprandial changes in hunger and satiety. This observation is compatible with our finding of similar postprandial cholecystokinin concentrations in all the subject groups. These results are in line with the normal postprandial cholecystokinin-33 concentrations previously reported in eight patients with anorexia nervosa, studied only in the underweight state (8).

Despite their profound weight loss and lack of hunger, the underweight patients with anorexia nervosa had normal basal plasma concentrations of cholecystokinin. This finding, combined with the finding of normal postprandial concentrations of the hormone in anorexia, does not support the hypothesis that low hunger levels in anorexic patients are due to abnormally high cholecystokinin secretion (9). However, our finding of high basal cholecystokinin concentrations, which normalized after weight restoration, in a single patient suggests that lack of appetite while fasting might be associated with inappropriate cholecystokinin secretion in a subgroup of patients. Larger studies will be required to assess this possibility.

We cannot rule out the possibility that greater than normal end organ sensitivity to cholecystokinin is involved in the high satiety ratings and low hunger ratings in anorexic patients. Hypercortisolemia, for example, might sensitize certain end organs to the effects of cholecystokinin (10). Use of specific cholecystokinin receptor antagonists will be required to address this issue. Furthermore, since cholecystokinin release is stimulated by delivery of nutrients into the duodenum, assessment of gastric emptying would be helpful in interpreting meal-stimulated cholecystokinin concentrations in plasma. Thus, if delayed gastric emptying were to be found in

anorexic patients in combination with normal cholecystokinin secretion, then even the normal cholecystokinin concentrations might be considered inappropriately high.

It is interesting that the significant enhancement of hunger and reduction of satiety observed in the anorexic patients after correction of their weight loss was not associated with any group change in cholecystokinin secretion, leaving open the possibility that cholecystokinin secretion in anorexic patients is dissociated from their appetitive sensations. In this regard, large, seemingly unpredictable intraindividual changes in cholecystokinin secretion between the low-weight and weight-corrected conditions were observed in the anorexic patients. The meaning of this variability in cholecystokinin secretion is unclear; however, it may represent an area of physiologic instability in anorexia nervosa, perhaps related to the predisposition of many anorexic patients to alternate between food restriction and binge eating. Detailed, longitudinal studies are needed to assess this possibility.

In summary, these findings indicate that, in contrast to patients with bulimia nervosa, the majority of patients with anorexia nervosa have normal fasting and postprandial plasma cholecystokinin levels. There were no observable relationships between body weight, nutritional status, and meal-provoked cholecystokinin secretion in this study. Accordingly, these data do not support the hypothesis that low hunger levels and high satiety ratings in patients with anorexia nervosa are due to hypersecretion of cholecystokinin into plasma,

although a small subgroup of anorexic patients with inappropriate cholecystokinin secretion may exist.

Replication of Action of Cholecystokinin Tetrapeptide in Panic Disorder: Clinical and Behavioral Findings

Jacques Bradwejn, M.D., Diana Koszycki, M.A., Richard Payeur, M.D.,
Michel Bourin, M.D., Dip.Pharm., and Heather Borthwick, M.D.

Eleven patients with panic disorder were challenged with cholecystokinin tetrapeptide (CCK-4) on two occasions. The effects of CCK-4 were consistent except symptom onset was more rapid with the second injection. Demonstrating that the effects of CCK-4 are reproducible in panic patients opens the door for studies of the effects of drug treatment on CCK-4-induced panic.

(Am J Psychiatry 1992; 149:962-964)

Recent studies (1-3) suggest that cholecystokinin tetrapeptide (CCK-4) could provide a pharmacologic model of panic attacks in humans. This is supported by findings that CCK-4 satisfies four criteria for a panicogenic agent: it seems safe for use in humans, it elicits both somatic and affective symptoms of a panic attack, it induces attacks that are similar to patients' usual attacks, and it precipitates panic attacks at a higher frequency in patients than in normal subjects.

To further establish the relevance of CCK-4 as a model anxiety- and panic-inducing agent, it is important to verify whether its effects are consistent and reproducible in multiple administrations. Fulfilling this criterion is essential for eventual studies of the effects of antipanic drugs, such as imipramine and alprazolam, on CCK-4-induced symptoms.

METHOD

Patients with DSM-III-R panic disorder with or without agoraphobia were selected from an anxiety disorders clinic. Other criteria were age between 18 and 65 years, good physical health, and at least two panic attacks per week for 3 weeks before entrance into the study. Low doses of benzodiazepines were permitted

throughout the study provided that the doses were not altered. The patients provided written informed consent for their participation, and the study was approved by appropriate ethical review boards.

The group included four men and seven women (median age=42 years, range=24-61). The median number of panic attacks during the week before the study was 10.0 (range=2-35), and the median duration of illness was 6.0 years (range=2-25). Eight patients were taking benzodiazepines at the time of the study: alprazolam, N=4 (mean dose=0.66 mg/day, SD=0.5); clonazepam, N=2 (mean dose=1.5 mg/day, SD=0.7); lorazepam, N=1 (2 mg/day); clonazepam plus lorazepam, N=1 (1 mg/day and 2 mg/day, respectively). These regimens did not change during the study, and the time of the last dose was kept constant.

We prepared the CCK-4, consisting of an amino acid chain of Trp-Met-Asp-Phe-NH₂, according to procedures published earlier (1). The patients were challenged with 25 µg i.v. of CCK-4 in a bolus push on two occasions, separated by a 2-3-day interval. On each occasion, the patient first received one injection of placebo (2.5 ml of 0.9% NaCl) followed by one injection of CCK-4 (injected in 2.5 ml of 0.9% NaCl). The second injection (CCK-4) was administered after the patient fully recovered from the first injection (placebo). The patients were blind to the order of the injections.

Immediately after each injection the patient was asked to describe the symptoms experienced since the injection. The onset, duration, and description of these symptoms were recorded by one of the investigators. On a scale of 0-4, each patient rated the intensity of the symptoms on a symptom checklist derived from DSM-III-R. Symptoms not appearing on the checklist but spontaneously reported by patients were also rated. The patient was then asked to compare the response to CCK-4 with clinical attacks and to report whether any novel symptoms had occurred with CCK-4. Two vari-

Fear of going crazy	0.9	1.6	0.4	1.2	0.8	1.5	0.3	0.9	—	n.s.

^aSignificant session effect for dyspnea ($F=9.80$, $df=1, 10$, $p<0.05$) and unreality/detachment ($F=5.38$, $df=1, 10$, $p<0.05$) (two-tailed probability).

ables were obtained from the checklist: 1) a score for the total number of symptoms (number of items scored 1 or higher) and 2) a sum intensity score (sum of intensity ratings of symptoms). To be defined as a panic attack, the symptoms had to meet the DSM-III-R criteria, including both somatic and affective symptoms of a panic attack, and had to be reported by the patient as a panic attack.

RESULTS

None of the symptoms induced by CCK-4 was reported as novel by any of the patients. The mean numbers of symptoms for the first and second sessions were, respectively, 11.8 (SD=4.0) and 11.2 (SD=5.2) for CCK-4 and 4.2 (SD=6.2) and 3.3 (SD=4.8) for placebo. The symptom intensity sums were 31.6 (SD=17.6) and 32.0 (SD=21.4) for CCK-4 and 11.2 (SD=17.8) and 6.5 (SD=13.4) for placebo. A Solution by Session analysis of variance with repeated measures revealed no significant difference between the initial and second challenge sessions in the number of symptoms ($F=1.31$, $df=1, 10$, $p<0.28$) or intensity sum ($F=1.21$, $df=1, 10$, $p<0.30$), regardless of solution administered (interactions were nonsignificant). In contrast, the number of reported symptoms ($F=86.10$, $df=1, 10$, $p<0.000$) and the symptom intensity sum ($F=55.46$, $df=1, 10$, $p<0.000$) were significantly higher with CCK-4 than with placebo for both sessions. A breakdown of symptoms induced with CCK-4 and placebo appears in table 1.

Changes in the onset and duration of symptoms were evaluated for CCK-4 only, by means of paired t tests. No significant increases or decreases in the mean duration of symptoms were found between the initial and

second injections: 5.8 (SD=4.8) versus 5.2 (SD=4.8) minutes ($t=1.25$, $df=10$, $p<0.24$), but the time before onset of symptoms was significantly shorter with the second CCK-4 injection: 26.3 (SD=7.2) versus 20.9 (SD=3.8) seconds ($t=2.77$, $df=10$, $p<0.02$).

The prevalences of panic attacks after the first and second CCK-4 injections were similar. The rate of panic was significantly greater with CCK-4 than with placebo for both sessions ($p<0.01$, binomial tests). In the initial challenge session, nine (81.8%) of the 11 patients panicked with CCK-4 and one (9.1%) panicked with placebo. In the second session, eight (72.7%) patients panicked with CCK-4 and one panicked with placebo. Eight patients (72.7%) panicked with both CCK-4 injections, and one panicked with both placebo injections.

DISCUSSION

This study demonstrates that the behavioral effects of CCK-4 are reproducible in patients with panic disorder. The main difference between testing sessions was that the onset of CCK-4-induced symptoms was more abrupt in the second session. This may be explained by a neuronal sensitization induced by CCK-4 or by an earlier recognition by patients of symptoms induced by the second CCK-4 injection. Further studies are needed to clarify this point.

Demonstrating that the effects of CCK-4 are reproducible in panic patients opens the door for studies on the effect of treatment with imipramine, alprazolam, or experimental drugs on CCK-4-induced panic. In animal models (4-8), CCK-4 is anxiogenic, its effects are antagonized by CCK receptor antagonists, and CCK an-

tagonists are anxiolytic. Research using the test-retest design reported here is now needed to evaluate whether CCK receptor antagonists can block the panicogenic effects of CCK-4 in panic disorder patients, and studies are needed to evaluate the therapeutic potential of CCK receptor antagonists.

Somatic Symptoms After a Natural Disaster: A Prospective Study

Javier I. Escobar, M.D., Glorisa Canino, Ph.D.,
Maritza Rubio-Stipec, M.S., and Milagros Bravo, Ph.D.

The authors prospectively examined the prevalence of somatization symptoms among community respondents after a natural disaster in Puerto Rico. Exposure to the disaster was related to a higher prevalence of medically unexplained physical symptoms, particularly gastrointestinal ones (abdominal pain, vomiting, nausea, excessive gas) and pseudoneurological ones (amnesia, paralysis, fainting, unusual spells/double vision).

(Am J Psychiatry 1992; 149:965-967)

Although the psychiatric literature consistently points to increased morbidity among persons exposed to disasters, most previous studies have not used structured formats or have been retrospective. In the only previous prospective study (1), the reinterviewing, with a structured interview, of subjects exposed to a series of disasters in St. Louis afforded a longitudinal view of the impact of disasters and revealed that such disasters were unlikely to initiate mental disorders or affect levels of new psychiatric symptoms. In that study, 43% of the subjects exposed to the disasters and 25% of those who were not exposed reported at least one new somatization symptom. Although not statistically significant, this observation was of interest to us, since we had theorized that somatic symptoms may serve as coping mechanisms or reflect enduring traits (2). A natural disaster affecting respondents who had been previously interviewed with a structured interview presented an opportunity to perform a prospective study to test these hypotheses further.

On Oct. 6 and 7, 1985, Puerto Rico was hit by severe flash floods and mudslides. This was one of the worst five such disasters affecting U.S. territories in the last two decades; it left at least 180 persons dead and thousands injured (3). The disaster occurred about a year after interviews had been completed as part of a Puerto Rican epidemiological survey (4).

METHOD

In the Puerto Rican survey, which used methods quite similar to those of studies in the United States, 1,551 adult respondents were interviewed in 1984 with a Spanish version of the Diagnostic Interview Schedule (DIS) (4). In 1987, about 1 year after the disaster, 912 respondents were interviewed with the same research instrument. Of these, 41% (N=375) were part of the original cohort interviewed in 1984. For this article, only data on the 375 respondents who were interviewed both before and after the disaster are included.

Three degrees of exposure (severe, moderate, and minimal) were defined on the basis of self-reports documenting the intensity of direct exposure to the disaster and the occurrence of calamities such as the death of a loved one, serious physical injury, or imminent physical threat to oneself or one's family. Of the 375 respondents interviewed twice with the DIS, 139 were classified as having been exposed to the disaster (they lived in the affected areas, experienced losses, or faced serious risk), and the remaining 236 were classified as unexposed.

In Puerto Rico, an aggregate of 12 somatic symptoms has been empirically derived from the DIS with the use of multivariate analyses (5). These include four pseudoneurological, four cardiorespiratory, and four gastrointestinal symptoms. For the statistical analyses reported in this article, we merged the data on the respondents with severe, moderate, and minimal exposure to the disaster (the exposed group) and contrasted them with the data on the unexposed respondents. We included only data on the 12 somatic symptoms and examined whether these symptoms were new or persistent. A new somatization symptom was defined as a symptom that was reported absent in 1984 but present in 1987; a persistent symptom was defined as one that was reported

^aWith Yates' correction.^bFisher's exact test (chi-square may not be applicable because of the low N in each cell).

present in both the 1984 and 1987 interviews. To be scored as present, a symptom had to meet severity criteria and, after probing by the interviewer, be judged unrelated to physical illness, physical injury, or the use of medication, drugs, or alcohol.

In the analyses, numbers of exposed and unexposed subjects reporting at least one new or persistent symptom were compared. Both new and persistent symptoms were broken down into pseudoneurological, cardiorespiratory, and gastrointestinal categories. Significant differences were established with the use of chi-square tests with Yates' correction.

RESULTS

Table 1 shows the number of exposed and unexposed respondents presenting any new or persistent somatization symptom at the time of the second interview. Overall, a higher proportion of exposed than unexposed subjects reported new or persistent symptoms. However, the only statistically significant differences were for new gastrointestinal and pseudoneurological symptoms. Thus, as shown in table 1, both types of new symptoms were more likely to be reported by subjects exposed to the disaster than by unexposed subjects.

DISCUSSION

Studies using the DIS have shown that when the same respondents are interviewed twice, about a year apart, there is a tendency to underreport symptoms in the second interview relative to the first (6). In contrast to such studies, we have demonstrated net increases in somatic and other types of psychiatric symptoms, but only when the second interview follows exposure to a disaster (7).

Our data indicate that somatic symptoms are an important component of the disaster-reactive psychopatho-

logical repertoire and that gastrointestinal and pseudoneurological ones are the most likely to emerge after exposure to a stressor. Gastrointestinal symptoms (abdominal pain, nausea, vomiting, excessive gas) are the somatic symptoms most commonly reported by community populations. Due in part to their high prevalences, these symptoms tend to be rather nonspecific. For example, increases in these symptoms may reflect a variety of psychiatric or physical states, and in the case of natural disasters, it is possible that these symptoms may also result from the unsanitary conditions that often follow such events. Pseudoneurological symptoms (amnesia, paralysis, fainting, and unusual spells/double vision), however, may be more specific indicators of stress responses than other symptoms. For example, these symptoms have low prevalences, have been traditionally linked to psychological distress, and are more commonly related to conversion disorder than to somatization disorder. It is interesting that two of these symptoms, fainting and unusual spells, are common characteristics of *ataque de nervios*, a culture-bound syndrome frequent among Puerto Rican populations and usually related to stressful events.

An advantage of assessing unexplained somatic symptoms as possible indicators of psychopathology among general populations is that they are more objective, easier to elicit, less likely to be subject to misunderstanding, and far less intrusive than questions addressing psychopathology more directly. An obstacle in eliciting these symptoms is their large number (there are 37 in *DSM-III-R*), since they have to be individually scrutinized. Grouping these symptoms on the basis of natural clusters may facilitate this process in the future and allow wider applications of these promising leads to the study of clinical and community populations.

The limitations of the data in this study are those inherent in epidemiological research in psychiatry, such as use of questionnaires administered by lay interviewers and total reliance on respondents' reports. Since Puerto Rico is a relatively small, self-contained area with

a high population density, it is conceivable that almost anyone residing in the island may have been directly or indirectly affected by the disaster. Therefore, differences in symptom presentation between the exposed and unexposed groups may have been attenuated. Also, the sample of exposed subjects was relatively small and the length of time that elapsed between the disaster and the interviews was rather long, so extraneous factors may have influenced the results.

ALCOHOLISM

Understanding and Treating Alcoholism, vol. 1: An Empirically Based Clinician's Handbook for the Treatment of Alcoholism, by Jill Littrell. Hillsdale, N.J., Lawrence Erlbaum Associates, 1991, 408 pp., \$75.00.

Understanding and Treating Alcoholism, vol. 2: Biological, Psychological, and Social Aspects of Alcohol Consumption and Abuse, by Jill Littrell. Hillsdale, N.J., Lawrence Erlbaum Associates, 1991, 311 pp., \$49.95 (\$99.95 for both volumes).

In 1981 Dr. Littrell completed her doctorate in clinical psychology and began working with alcoholics. She heard a great deal of allegedly factual information about alcoholism from both therapists and patients, but, as a scientist, she wondered what was really true. These two volumes are her attempt to give others the empirical findings on alcoholism that she wished were available to her when she began her work with alcoholics more than 10 years ago. She has succeeded admirably. These books are a great addition to the literature on alcoholism and will be an important resource for therapists and researchers alike.

I will mention some of the conclusions from each volume. In volume 1, Dr. Littrell discusses empirical findings relating to Alcoholics Anonymous (AA) as a treatment. Since some see AA as the treatment of choice but others think of it as a substitute illness, it is important to know what the real situation is. Her findings here, like many in the book, show that there are no simple answers, that the results depend on several variables. For example, AA works best, she finds, with alcoholics who are authoritarian, religious, and opposed to controlled drinking. Those who seek out AA tend to be gregarious and to have been better adjusted in childhood than other alcoholics but lacking in social support as adults.

Dr. Littrell notes that there is a high treatment dropout rate among alcoholics. As many as one-third of intake patients fail to return for treatment. Thus, the defensiveness that drug users often display is shown in the failure of alcoholics to engage in treatment, even though they may have gone for an intake interview.

The MMPI is possibly the best personality test in psychology, and the author presents many findings relating to alcoholism and the MMPI. For example, two types of MMPI profiles have been found for wives of alcoholic men. One group seems to be anxious and depressed (elevated profiles on depression, psychasthenia, and hysteria scales), and the other group scores high on the psychopathic deviate scale. In traditional terms, the first group of wives seems to be neurotic and the second group seems to have character disorders. This does not necessarily mean that these women are mentally disordered but, rather, that they show traces of neurotic or psychopathic qualities. Some may be mentally disordered. Also, some may have been this way before they encountered the alcoholic and others may show these patterns in response to living with an alcoholic.

Volume 2 has some important insights that many may not know about. For example, the reader may think that twin studies have either proven the genetic basis of alcoholism or at least can easily do so. However, things are not quite this simple. For one thing, monozygotic twins tend to live in a common residence longer than dizygotic twins, so heredity and environment are confounded. For another, twin studies fail to examine types of alcoholism, such as primary alcoholism, which seems to be independent of additional psychopathology, and secondary alcoholism, which is preceded in time by another primary disorder, such as antisocial personality disorder or depression. Thus, twin studies are not definitive for showing the inheritance of alcoholism, although they tend to support the view that alcoholism is inherited. Even here another caveat is in order: the results for inheritance of alcoholism is clearer in the case of males than it is in the case of females.

Even if alcoholism is an inherited disorder, cognitive and social factors play roles in its development. Dr. Littrell does an excellent job of discussing these variables, which include attitudes and expectancies as well as gender. For example, she reports that the estimated alcoholism rate for males is 10%, compared with 5% for females. Higher rates of alcoholism are found among nonwhites, Protestants, the lower classes, and individuals who are divorced, separated, or single. Thus, it is clear that social factors interact with any inherited tendencies to produce alcoholism.

The findings on alcohol and sexuality are interesting. Both men and women have subjective increases in sexual arousal after drinking alcohol, and this seems due to expectancies as well as to pharmacological effects. Initially, people have greater physical sexual arousal from alcohol, but sexual physiological functioning is reduced with increased dosages. Men drinking an alcohol placebo experience greater penile tumescence, but women do not show greater physical sexual arousal in response to an alcohol placebo. Both men and women show strong subjective reactions to alcohol, indicating the power of expectation. We expect alcohol to make us less inhibited sexually; this is a powerful belief that can serve as a self-fulfilling prophecy.

These two volumes are excellent and will add greatly to the knowledge of anyone concerned with alcohol and alcoholism. The volumes are so good that I recommend them despite their cost.

RUSSELL EISENMAN, PH.D.
Lake Charles, La.

CHILDREN AND THE ELDERLY

Disorders of Learning in Childhood, by Archie A. Silver and Rosa A. Hagin. New York, John Wiley & Sons, 1990, 683 pp., \$65.00.

Depending on the definition and the methods used for estimating its prevalence, learning disability is a problem that may

affect between 5% and 30% of schoolchildren. Indeed, at least 5% of all elementary schoolchildren in the United States receive special education services for learning disabilities. This book is about these children as well as others who are academic failures.

In part one, the authors present their argument that the term "learning disorders" rather than "learning disabilities" should be used because it is more descriptive of the population that is the focus of their book. This population includes "all children whose academic achievement is below that expected from their age and intelligence" (p. 25). Thus, the book is very broad in scope and includes children with a number of childhood disorders that typically are not thought to be subsumed under the term "learning disabilities." Further, the authors consider the voluminous data on subtyping of children with learning disabilities and suggest that the unifying concept basic to all subtype differences is the children's difficulties with spatial orientation and/or temporal organization.

In part two, the authors present a rich array of methods, procedures, and protocols based on their years of clinical and research work in the management of children with learning disorders. Included are excellent chapters on educational and psychological assessment and management that present a wealth of information on a wide variety of methods, including a number of new and innovative techniques (e.g., reading recovery). Based on their own experience, the authors recommend a five-step decision-making process to evaluate 1) educational achievement, 2) educational opportunity, 3) sensory acuity, 4) cognitive functioning, and 5) neuropsychiatric functioning. An integration of data from these assessments provides the basis for designing appropriate intervention strategies. There is a chapter on the effects of drugs on learning and memory that includes the traditional medications as well as the nootropics (e.g., piracetam) purported to enhance learning and verbal memory in children with specific learning disability. This is followed by a chapter on psychotherapy that is based mainly on the authors' own casework rather than on the research literature. One suspects that this approach was undertaken because of the dearth of good research on the effects of psychotherapy in this population. Indeed, this points to the need for research in this area. Finally, there is a chapter on prevention of disorders of learning. This is a nice touch because this topic is seldom included in textbooks and, as noted by the authors, prevention has not been an area of much research interest.

Part three deals with clinical patterns in disorders of learning. In six chapters the authors cover the nature, cause, and remediation of such disorders as specific language disability, attention deficit hyperactivity disorder, Gilles de la Tourette's syndrome, and autism. They also include chapters on children who display the effects of poverty, cultural differences, and inappropriate stimulation. Each of the chapters is detailed, draws on knowledge from a number of different disciplines, and provides an integrated framework that will help clinicians to design appropriate treatment protocols. Part four, arguably the best section of the book, presents the authors' vision of future research and services in this field.

This book represents the personal statement of two highly respected clinicians and scholars who have been active in the field of learning disorders for several decades. It is full of descriptions of their own work and that of their colleagues and includes personal communications that date as far back as 1936. It is the sort of book that one would expect from scholars in the twilight of their academic careers—a cross between didactic and academic presentation, with just a hint of dogmatism when it comes to what they consider to be good clinical

practice. It is full of wisdom that comes only from years of clinical experience and dedication to the field.

NIRBHAY N. SINGH, PH.D.
Richmond, Va.

Delirium in the Elderly, by James Lindesay, Alastair MacDon-
ald, and Ian Starke. New York, Oxford University Press,
1990, 122 pp., \$45.00.

Psychiatry has been waiting a long time for a book on dementia in the elderly. The result of a collaboration by two psychogeriatricians and a geriatrician (all British), *Delirium in the Elderly* exemplifies the cooperative approach it espouses. A small, readable book of six chapters, it is a pleasing combination of thoroughness and pragmatism, British in its modesty and international in its citations.

Thoroughness is the hallmark of the first chapter, which deals with the concept of delirium. The authors deal here with the issue of definition, which they revisit in the final chapter, which concerns an agenda for research. They point out that we do not yet have an agreed-on definition of delirium and that theoretical difficulties between *DSM-III* and *ICD-10* continue even though they are broadly comparable. These difficulties include the fact that *DSM-III* allows the diagnosis of dementia only when a physical cause can be demonstrated (or, in *DSM-III-R*, presumed) and the fact that *ICD-10* requires that the outcome be known (duration less than 6 months). The authors argue that these difficulties prevent *DSM-III* and *ICD-10* criteria from being used in etiological research. They propose that delirium be strictly regarded as a syndrome and offer their own, less constrained definition.

The second chapter deals with clinical assessment. The advantages of visiting the home are listed, and a schedule for use with informants and a copy of the Mini-Mental State Examination are provided.

The third chapter considers the causes of delirium and is a splendid review of the organic factors. The authors remind us that there is no identifiable organic cause for dementia in a proportion of delirious patients. They observe that psychiatric, psychological, and environmental factors may play a part in delirium and that these may result in physical complications such as dehydration and psychotropic drug use.

The fourth chapter explores the neuronal basis of delirium. It closes with hypotheses regarding hypoactive delirium due to cholinergic dysfunction or due to monoaminergic dysfunction. Hypoactive delirium due to cholinergic dysfunction involves slowing of the EEG, and hypoactive delirium due to monoaminergic dysfunction involves an essentially normal EEG with paroxysmal bursts of fast activity.

The fifth chapter deals with management, including clear and useful diagrams and lists of how to investigate. The section on psychotropic drug treatment is a little too brief, perhaps in an effort to play down the importance of psychotropic medication in dementia. The authors make the point that haloperidol can lead to tardive dyskinesia, but this is not mentioned as a side effect of the other psychotropics, and they describe thioridazine as "probably the most troublesome drug in the elderly." What has happened here is that the biases of the authors do not match my own.

This scholarly book has much for psychogeriatricians, geriatricians, and students in these fields. The preface states that the aim is not only to present knowledge but also to reveal our ignorance. It closes playfully with the statement, "The sooner this edition is out of date, the better." That may come to pass

in the regrettably distant future, at which time it is hoped these authors can be pressed into producing a second edition.

SAXBY PRIDMORE, M.D.
Hobart, Australia

SEXUALITY

Homosexuality/Heterosexuality: Concepts of Sexual Orientation, edited by David P. McWhirter, M.D., Stephanie A. Sanders, Ph.D., and June Machover Reinisch, Ph.D. New York, Oxford University Press, 1990, 423 pp., \$49.95.

Evelyn Hooker and Mary Ziemba-Davis state in their epilogue to this book that "prejudice, even among scientists, dies hard. As this volume demonstrates, however, Dr. Kinsey has at last come into a full measure of acceptance" (p. 401). *Homosexuality/Heterosexuality*, published as the second volume in the Kinsey Institute Series, is a collection of chapters written by the participants in a Kinsey Symposium convened to mark the 50th anniversary of the Kinsey 7-point scale to describe the heterosexual/homosexual continuum of behavior. The book provides an outstanding overview of current thinking in relation to sexual orientation, and its publication serves not only as a sign of the widespread acceptance of Kinsey's pioneering efforts in studying human sexuality but also as a marker of the radical changes in views of sexual orientation that have occurred since the publication of the Kinsey volumes on sexuality in men (1) and women (2).

The editors of this volume are particularly well-qualified to compile a book on sexual orientation, and they have brought together an outstanding group of authors to comment on the significance of Kinsey's work and to expand on its theoretical implications for a modern understanding of sexual orientation. As a result of the authors' breadth of expertise and the multidisciplinary focus of the text, this book provides a helpful synthesis of new information and data about sexual orientation, especially homosexuality, that should be of interest to all psychiatrists and other mental health professionals, particularly those who work in the area of sexuality.

The chapters are divided into sections that provide accounts of historical and religious, psychobiological, evolutionary, cultural and sociological, identity development, relational, and conceptual perspectives on sexual orientation. Chapters by Louis Gooren on "Biomedical Theories of Sexual Orientation," Eli Coleman on "Toward a Synthetic Understanding of Sexual Orientation," Richard Isay on "Psychoanalytic Theory and the Therapy of Gay Men," and Philip Blumstein and Pepper Schwartz on "Intimate Relationships and the Creation of Sexuality" may be of particular interest to the clinician.

Several chapters stand out in this collection of uniformly interesting selections. The overview, written by the editors, is a helpful summary of many complicated concepts related to sexual orientation and provides a succinct guide to the other chapters in the volume. The chapters by Vern Bullough, "The Kinsey Scale in Historical Perspective," and John Gagnon, "Gender Preference in Erotic Relations: The Kinsey Scale and Sexual Scripts," are clearly the products of senior and erudite scholars in the field of human sexuality who demonstrate an enormous knowledge of and fascination with their subjects. Gilbert Herdt's chapter, "Developmental Discontinuities and Sexual Orientation Across Cultures," and Letitia Anne Peplau and Susan Cochran's chapter, "A Relational Perspective on

Homosexuality," also provide clear and useful insights into their topics.

Although there are few weaknesses in this volume, it is unfortunate (and unacknowledged) that some chapters, such as those by Eli Coleman and John Money, are recycled versions of previously published articles, but even these chapters provide valuable information for the reader who is new to this field. The relative absence of specific discussions of women, except for the chapter on lesbian relationships by Margaret Nichols, reflects a larger tendency in the field to ignore the study of women's sexual orientation.

A major theme of *Homosexuality/Heterosexuality* is "a cry to elaborate the qualitative characteristics of people in a given category" (p. 401). This book is a fitting tribute to Kinsey's monumental contributions to defining the modern study of human sexuality. It responds to the cry for elaboration of the characteristics associated with men and women who have a particular sexual orientation by delving deeply into the increasingly sophisticated knowledge of the multidimensional nature of sexual desire and reminding us of the variable and unique expressions of sexuality among individuals. It further demonstrates that we can no longer use categorical and dichotomous labels such as homosexuality and heterosexuality, which are derived from a unidimensional conceptualization of sexual orientation, to describe the sexuality of groups of people.

Many of the contributors to this volume argue for a new understanding of sexual orientation that will integrate the multiple biological, psychological, and social factors shaping human sexuality and will express the complex emotional, cognitive, behavioral, and interpersonal meanings associated with sexual orientation in the lives of individual men and women. It is likely that at least some of the text for this new understanding will come from several of the authors in this volume, who demonstrate how essential Kinsey's work was in leading to our current level of understanding about human sexuality, how far we have moved beyond the work of this seminal thinker, and how much we still have to explore about this most fundamental aspect of human experience. It is a tribute to the editors and authors of this excellent compendium that the first thought that may come to the mind of the reader on completing it is, "I can't wait for the sequel to be published."

East Lansing, Mich.

HISTORY OF PSYCHIATRY

The American Board of Psychiatry and Neurology: The First Fifty Years, edited by Marc H. Hollender, M.D. Evanston, Ill., ABPN, 1991, 173 pp., no price listed.

The public expects a profession to demonstrate that its members have been assessed and have met certain standards of performance and expertise. The profession thus assures the public that it assesses itself in order to set and maintain stand-

ards internally rather than having them imposed by external agencies. The American Board of Psychiatry and Neurology was founded for this purpose in 1934, and the first certifying examinations took place in Philadelphia on June 7, 1935. This book recounts the history of the first half-century of the Board's deliberations, thought processes, relationships with other professional boards and organizations, etc. It is a complicated history and is well documented, providing us with the experience and deliberations of leaders in the field of psychiatry on many questions that our profession still faces, such as the relationship between psychiatry and neurology, recertification, self-assessment of practitioners, setting standards for training programs, and setting standards for practicing psychiatrists.

The book is well laid out, proceeding from the reason for the establishment of the Board through the relationship between psychiatry and neurology, the development of the examinations in both specialties, certification in subspecialties, educational "essentials" for postgraduate training, and recertification. The reasons for combining psychiatry and neurology in one board are discussed, and in his preface Dr. Hollender notes that "the problems resulting from bringing psychiatry and neurology together appeared at the very outset and were numerous and divisive" (p. ix). The gradual separation of the examination into two separate examinations is discussed. By the 1980s, Dr. Hollender notes, "Paradoxically, the divergence became greatest when scientific and clinical advances in the two specialties might have been expected to draw them closer together. The large number of psychiatry candidates and the relatively small number of neurology examiners were responsible for the logistics that promoted the separation" (p. x). The shifts and changes in the content covered by the Board examinations have reflected the many changes in the knowledge and practice of both specialties. Future decisions of the Board about the content of the examinations will undoubtedly reflect the rapidly increasing knowledge in the neurosciences, and the examinations in psychiatry and neurology may once again overlap.

Dr. Hollender's chapter on the history of the internship and S. Mouchly Small's chapter on recertification are particularly informative because the authors discuss the wide range of factors, including pressures from society and the medical professions as a whole, that influence policy decisions. The issue of recertification is clearly not resolved and will eventually have to be dealt with by the Board.

The appendixes list the directors of the Board for its first 52 years (1934–1985), a veritable Who's Who of psychiatry, and present data about the number of certificates issued each year (the data for 1956 and 1957 are missing) and the percent of candidates who passed from 1974 through 1985. I could find no reason that the percent passed was not given for all 52 years and feel it would have made the book a more complete historical document. Also, the data for diplomates in child psychiatry and neurology with special qualification in child neurology lists the number of individuals grandfathered in, but no such data are given for the diplomates in psychiatry or neurology. I was able to determine, combining data given on page 31 and in the appendixes, that 107 certificates were given the first year (1935), that 86 were grandfathered, and that 21 (68%) of 31 candidates passed.

A chapter on the research done on the different types of assessment used in past Board examinations would have contributed to the research literature on assessment. These research findings were used in making the decisions to give a written multiple choice examination as Part I, not to use es-

says, to drop some of the oral examinations, to establish training for the examiners of Part II, and to use both live patients and videotapes. These are important decisions based on sound research on assessment. Additionally, an appendix consisting of the content covered in both the written and oral examinations over the years would have been an excellent addition.

This book serves a very useful purpose as documentation of the history of an important part of our profession. It should be read by anyone who is examining or going to examine for the Board who wants an in-depth perspective of the meaning, purpose, and development of the process. The historical perspective of this book is a resource for members of our profession who are involved in setting policy about recertification, about knowledge that is required for certification, and about standards for training in postgraduate training. All residency programs should have this book in their libraries as part of the literature on the history of psychiatry.

The Private War of Mrs. Packard, by Barbara Sapinsley. New York, Paragon House, 1991, 210 pp., \$19.95.

Barbara Sapinsley tells the story of Elizabeth Parsons Ware Packard (1816–1897), whose involuntary admission to the Illinois State Hospital for the Insane at Jacksonville at the behest of her husband, the Reverend Theophilus Packard, Jr., subsequently led her to successfully campaign for changes in civil commitment laws across the United States. Ms. Sapinsley provides us with a readable volume that, despite the author's claim, does not exactly rescue Mrs. Packard from obscurity. E.P.W. Packard has been the object of attention of Phyllis Chesler (1), Alan Dershowitz (2), and Thomas Szasz (3). Unlike these and other authors who have tackled the subject of Mrs. Packard, Ms. Sapinsley had access to Mrs. Packard's descendants and to the diaries, journals, and other documents of several generations. What more do we learn from this treatise?

We learn less than we might because Ms. Sapinsley decided not to name sources—there are no footnotes, no notes for each chapter, no list of references. The absence of sources is a problem not only for scholars who would be interested in pursuing further study but also for the general reader. One often cannot tell when statements are being made by Mrs. Packard from her nineteenth-century outlook and when observations are being made by Ms. Sapinsley from her modern perspective. In fact, much is simply paraphrased directly from Mrs. Packard's books. For example, Ms. Sapinsley writes,

The stove cleaning became a festive occasion for the fun-starved children. They insisted that "Black Prince" now shone as brightly as he had when their mother was housekeeper. After the job was done, they cleaned themselves up and then went to Elizabeth's room to warm up before retiring. Theophilus hastily gathered up his books and papers and withdrew. In his hurry, he left behind a bundle of letters which he apparently didn't miss and Elizabeth didn't notice until later.

At first she put them aside. After all, the letters were his and she had no right to pry. But then she decided that under her present circumstances, forewarned was forearmed and anything that gave her an advantage in self-protection and self-defense was legal as well as

moral. So she read them. Then, to make sure she had read aright, she read them again, and panicked.

The letters were from Dr. McFarland, Theophilus's sisters, and a Dr. Prince, head of an asylum in Northampton, Massachusetts, which did not demand curability as a condition of admission (p. 108).

Mrs. Packard's original rendition is as follows:

When our merry polishing party had completed their task to their entire satisfaction, insisting upon it that "Black Prince" looked now just as bright as he used to shine when mother was housekeeper, we cleaned ourselves and all retired to my room to warm before retiring for the night. Our entrance was the signal for Mr. Packard's leaving, of course, and in his haste or carelessness in gathering up his papers he overlooked a package of letters, which he left behind upon my table. These I did not notice until all had dispersed and Mr. Packard had locked me up for the night.

My first thought was not to examine them, as they were undoubtedly left by mistake. But upon second thought I concluded it not only right to see my husband's papers, but also to avail myself of every lawful means of self-defense which lay within my reach. Accordingly I spent several hours of this night in carefully reading these letters, received during my incarceration and since my discharge. From these replies to his own letters, his platform of action, both past, present, and future, was distinctly portrayed, bearing most fearful and unmistakable evidence that I was to be entered in a few days into Northampton Insane Asylum for life!

One of these letters from Doctor Prince, Superintendent of that Asylum, assured me of this fact. (4, p. 17).

Nor does Ms. Sapinsley differentiate Mrs. Packard's beliefs about what might happen from what history shows us might have happened. Ms. Sapinsley notes that "Dr. Prince could then lock her up for life." This view might have been appropriate for Mrs. Packard, but Ms. Sapinsley should have told us that had Mrs. Packard arrived at Northampton State Hospital, within months Dr. Prince would be dismissed due to his poor management. Pliny Earle became the superintendent, and Dr. Earle might well have agreed with Mrs. Packard that she did not require continued hospitalization and discharged her (5).

Not only does Ms. Sapinsley fail to provide a historical perspective to Mrs. Packard's treatment, she misses interesting aspects of Mrs. Packard's progenitors, despite her rich source material. For example, there was considerable turmoil between Reverend and Mrs. Packard in regard to their repeated tarnishing of each other's reputations. It is perhaps ironic, and perhaps revealing of family dynamics, that E.P.W. Packard's father-in-law had years earlier delivered a sermon on the evils of slander. Neither son nor daughter-in-law heeded his counsel:

You perceive the effect, when you look at a house, when happiness is banished, and domestic warfare reigns with all its train of miseries; here a man's foes are they of his own household . . . We remark again, that the practice of slander and raillery defeats its own object. (6, pp. 9, 14).

Ms. Sapinsley does present the reader with previously un-

published material. Noteworthy among these is a description of Mrs. Packard's admission at age 19 to Worcester State Hospital for 6 weeks and quotations from her record at that institution. One assumes that Ms. Sapinsley obtained this material from (or with the authorization of) family members, since previous researchers have been denied access to this record by the Massachusetts Department of Mental Health (7). Although not a criticism of the book per se, the question of the use of this material is an interesting one. Since E.P.W. Packard fails to mention this hospitalization in any of her books, the specter of who releases such data raises its ugly head once again. Should the record of a hospitalization of an individual who chose not to disclose this material in her own books be available on family authorization? Does it matter that the record is now 156 years old? What is the difference between this and the Anne Sexton tapes (8)?

Ms. Sapinsley provides a modern feminist perspective to the Packard story, adding commentary that is sometimes informative, sometimes intrusive. She makes remarks about what Mrs. Packard's life and mission have meant to psychiatrists, saying that she was known in the psychiatric profession largely because of the hackles she raised—and still sometimes does. Without sources, we have no way to evaluate such comments.

Ms. Sapinsley is less a historian and less an analyst than she is a storyteller. She has tough competition, however, because Mrs. Packard was herself a most skillful storyteller. But Mrs. Packard's works (and she related her history in several published versions) are not easily found. Since few will be able to read the originals, Ms. Sapinsley's version, despite its problems, should serve psychiatry well.

PSYCHIATRIC TEXTBOOKS

Synopsis of Psychiatry: Behavioral Sciences and Clinical Psychiatry, 6th ed., by Harold I. Kaplan, M.D., and Benjamin J. Sadock, M.D. Baltimore, Williams & Wilkins, 1991, 903 pp., \$44.00.

An enticing soft cover in black with gold titles inside red-lined frames greets the reader's eye as the sixth edition of the *Synopsis* in 20 years heralds a renaissance of sorts for the "eclectic and multidisciplinary approach." In fact, the preface

is an eloquent promise to foster "the humane and compassionate aspects of medicine," so that the United States can avoid producing "computer-like, robotic physicians." Who would not wholeheartedly endorse the consideration of "the whole patient" and the study of the "sociopolitical forces that affect medical practice"? The stage is grandly set for an intellectual feat. Does the product then live up to the expectations of the consumer? I would answer by purposefully misquoting one of Spinoza's most famous statements: "I do not presume that I understand the true philosophy, I know that I have found the best philosophy" (1, p. 17).

Kaplan and Sadock envision a "teaching system" built on the durable *Comprehensive Textbook of Psychiatry*, the 5th edition of which appeared in 1989 (2). Building blocks of the system will be this *Synopsis*, a study guide, a pocket handbook, and a comprehensive glossary of psychiatric and psychological terms. The assistance of the venerable American Board of Psychiatry and Neurology and the National Board of Medical Examiners helps this volume to reach a worldwide readership. The text has been translated by now into five foreign languages. Without a doubt the vision is imposing, the landmarks glowing, the road very inviting. Thus we must enter into the foundation building.

The structure is made out of 48 chapters, the first one most appropriately titled "The Doctor-Patient Relationship" but conceptualized essentially as the typical psychiatric interview. The flow of chapters is good, but one wonders why the book was not divided into six obvious sections: basic sciences, clinical examination, adult clinical psychiatry, treatment approaches, child and adolescent psychiatry, and special areas such as geriatrics, forensics, ethics, and the history of psychiatry. Well-advertised and well-executed major changes and innovations are introduced in areas such as biological therapies, brain and behavior, the life cycle, geriatric psychiatry, AIDS, and nosology and diagnosis. I particularly liked an excellent comparative table of contributions to the life cycle study, beautiful figures and illustrations in the chapter on brain and behavior, useful comparisons of psychometric and neuropsychological tests, and a thorough list of the main psychiatric rating scales. From a clinical perspective, the discussion of temporal lobe epilepsy psychosis is an excellent piece, as are the chapters on AIDS, psychoactive-substance-induced mental disorders, and substance use disorders. Chapters on recent clinical observations such as the coexistence of anxiety and depression and chapters on sleep disorders, factitious disorders, impulse control, and adjustment disorders live up to their billing. The text on biological therapies is particularly strong and very well done. The same is true for the chapters on mental retardation, developmental disorders, anxiety disorders of childhood and adolescence, gender identity, and other disorders of infancy, childhood, and adolescence. I found the sections on special areas of child psychiatry (mood disorders and child abuse) and the chapter on psychiatric treatment of children and adolescents quite well-written and instructive. The same goes for the sections on forensic psychiatry and psychiatric ethics. The psychotherapeutic drug identification guide, which contains full-color illustrations of all the major drugs used in psychiatry in various dosage forms, is simply captivating, even though it could have been better placed in the psychopharmacology chapter.

So, is there something wrong with this sixth edition? The answer is almost a whisper: "No, but." What makes it a little less than a resounding success could be seen, from a different perspective, as the main strengths of the volume, namely, its appeal to different levels of readers and its all-encompassing, clear-cut, precise outlining of the different and complex areas

of our precious discipline. In doing that, the *Synopsis* smacks, at times, of vagueness and overgeneralization, omits some precise data, and gives the false impression of thoroughness and ultimateness, with self-contained units that do not even have adequate cross-references. Thus, it leaves little room for dissension, doubts, and ambiguity, so central to the contributions of authors such as Jerome Frank, van Praag, Kuhn, and Torrey. It creates what Schoolman (3) would call a "coercion for conformity . . . [that will] destroy the essential environment of fostering controversy, welcoming iconoclasm and providing refuge and a forum for rebels" (p. 89). In short, I missed a chapter on current controversies in psychiatry. An eloquent example of this is the omission of names such as Anna Freud, René Spitz, Karl Jaspers, and Kurt Schneider from the dry chronological history of the last chapter (my biggest disappointment). In spite of proclaiming that events are more important than individuals, only 15 events are listed in this chronology of 123 items. In addition, a pervasive blank in the promised "wholistic" approach is the role of social and cultural factors in psychiatric theory, psychopathology, research, and education. There is not much about the "sociopolitical forces" at play in the practice of psychiatry either, and the view of the whole discipline is inevitably tinged by the Northern Hemisphere-Western-Anglo-American view of the world, psychiatric and otherwise. I guess the *Synopsis*, like many other American books, cannot quite solve the dilemmas of whom to address the product to and how to package it. Although attempting to reach the whole world (as indeed it will, and justifiably so), the book cannot shake off an essentially American flavor.

Errors, omissions, and incomplete and ambiguous data appear here and there as little specks on an otherwise harmonious canvas. The International Pilot Study of Schizophrenia did not include Hutterites, Croats, or Tongans; some clinicians would disagree with the definition of dysphoria as merely "an unpleasant mood"; Hamilton's paper on assessment of anxiety states is said to have been published in a nonexistent British journal; tuberculosis is not a viral infection; and using interpretative psychotherapy in rheumatoid arthritis sounds as wrong as misspelling "geophagia" twice.

To devote only two paragraphs to the *International Classification of Diseases* betrays the purpose of updating the nosological advancements in the field. Jaspers and Kretschmer are not mentioned in the chapter on schizophrenia, and the Tsuang-Winokur criteria are also omitted. The list of culture-bound syndromes is obviously incomplete. Cushing's disease, hyperparathyroidism, and liver transplant are not mentioned in the chapter on psychosomatic disorders. Another gross omission is the lack of mention of cultural and social factors in the development of personality disorders. A table of the main brief psychotherapies and a listing of drug-drug interactions would have been helpful.

The discussion of dysthymia is incomplete because no mention is made of its close connection to borderline personality disorder; the assessment of obsessive-compulsive disorder and its treatment does not include neuropsychological testing or the use of augmenters. Many will frown when reading that psychotherapy is useful for delusional disorder and that insight-oriented psychotherapy is advocated for paraphilias, some of which are clearly associated with psychosis. Likewise, one is not sure whether depersonalization is a symptom or a syndrome, even though we know that it can be both. Finally, when supportive psychotherapy is considered a form of psychoanalytically oriented psychotherapy, our doubts threaten to become almost unsurmountable.

There are soothing passages, however. It is nice to see nine

pictures of Freud and his life, no matter how a lot or a little biased that may appear. It is a different kind of bias to equate anxiety with autonomic neuroendocrine reactivity, but to see the end of the psychoanalytical emphasis on anorexia nervosa is reassuring. Somebody may think that mixing vignettes with study series may be forgivable, but not when the standard warning about the simultaneous use of monoamine oxidase inhibitors and tricyclic antidepressants is omitted, or when a table of differential diagnosis in psychiatric emergencies and a picture of a brain with Alzheimer's disease are duplicated.

Enough for the picky evaluation of a book that, although imperfect like psychiatry itself, is full of excellent pages. Some people may even say that the purpose of this volume is not what this review seems to demand. Still, if somebody asks me whether I would choose this book to find useful information, the answer is a resounding yes. The book does justice to what Dr. Nemiah would tell us about the vastness and the richness of this discipline of ours (4). If the *Synopsis* does not have the answer we are looking for, there is always the *Comprehensive Textbook of Psychiatry*, or the intangible wisdom of our own patients, always ready to lead us out of our uncertainties and our ignorance.

Principles of the Psychiatric Evaluation, by Roger A. MacKinnon, M.D., and Stuart C. Yudofsky, M.D. Philadelphia, J.B. Lippincott Co., 309 pp., \$29.95 (paper).

This book is the retitled but largely unchanged revised edition of Drs. MacKinnon and Yudofsky's 1986 work, *The Psychiatric Evaluation in Clinical Practice*. This updated edition builds on the strengths of the original; it is at once comprehensive yet succinct, opinionated yet not doctrinaire. Drs. MacKinnon and Yudofsky are noted individually for their work in the fields of psychoanalysis and neuropsychiatry, respectively, and their collaboration here manages to be integrative where other comparable textbooks are limited; therein lies this book's particular value.

Chapters 1 and 2 are devoted to the psychiatric interview and the clinical examination of the patient. The discussion of the psychiatric interview includes nuts and bolts observations—about seating arrangements and note taking, for example—as well as more theoretical concerns such as transference and countertransference phenomena in a first meeting. The chapter on the clinical examination focuses on the psychiatric history and the mental status examination and includes an extensive inventory developed for the written history that should be useful for beginning residents, given its wide scope. Complementing the review of the mental status examination

is a discussion of two examples that underscore common pitfalls in its execution and interpretation.

Chapter 3 is an ambitious attempt to catalog the wide range of biological tests now available to psychiatrists. Familiar topics included are neuroendocrine assays, brain imaging techniques, and electroencephalogram diagnosis. The review of pharmacotherapy briefly addresses critical points in the initiation and monitoring of treatment with better-known medications as well as newer ones such as clozapine. Finally, the authors have added to this edition a timely set of guidelines to use in consideration of testing for HIV.

Chapter 4 focuses on the localization of brain function as well as psychopathology associated with diffuse cortical impairment, and chapter 5 lists a number of psychological tests and psychiatric rating scales. Some of the frequently used intelligence evaluators, personality tests, and neuropsychological batteries are outlined, among them the WAIS-R, WISC-R, Rorschach, Thematic Apperception Test, MMPI, and Halstead-Reitan. In the chapter appendix, seven psychiatric rating scales are reproduced, including the Beck Depression Inventory and the Hamilton Rating Scale for Anxiety. Given their wide use as research tools, it makes sense to include such familiar scales.

The sixth and last chapter is devoted to *DSM-III-R* diagnosis and psychodynamic case formulation. An extensive consideration of the written psychodynamic case formulation follows a brief review of the multiaxial evaluation according to *DSM-III-R*. This examination of key psychodynamic topics (ego functions, Freud's tripartite model, a scheme for symptom formation) ought to be easily understood by a beginning resident in the throws of his or her first case formulation. Three complete examples of case formulations follow this discussion.

Any text attempting to cover all of modern psychiatry in slightly more than 300 pages will be plagued by omissions; in this case some, like the dearth of information on tardive dyskinesia, are more glaring than others. The authors, however, take into account the inherent shortcomings of so broad a project by providing extensive bibliographies after each chapter. The breadth of material covered makes this volume indispensable for the trainee building a collection of references. Its wide scope also highly recommends the book to nonpsychiatrists interested in the current trends in psychiatric treatment. The particular value to psychiatry trainees of this and similar texts that stand resolute in their efforts to synthesize the biological and the psychodynamic cannot be overestimated.

Chicago, Ill.

RELIGION

The Divine Archetype: The Sociobiology and Psychology of Religion, by Brant Wenegrat. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1990, 207 pp., \$29.95.

For many, sociobiology is not of great interest; most of the standard psychiatric textbooks do not discuss it. However, to its adherents it is essential to understanding how humans behave. Sociobiologists study social behaviors of animals on the assumption that human behaviors have evolved from lower forms of life by means of evolution over the millennia.

This book arranges a marriage of psychoanalytic and neo-Darwinian theory to explain the origins of the religions of mankind. The author concludes that just as species-specific

animal behaviors have evolved which enhance adaptation of the species, so has mankind evolved religious beliefs to help members of our species sort out their sexual conflicts, promote cooperation, and encourage altruism.

If one wants to find out about sociobiology, this is an excellent place to start. There is a chapter that summarizes much of what sociobiologists talk about. There are 500 references in the bibliography. There is an interesting appendix, with summaries of numerous published case histories in which religious preoccupations were mixed in with serious psychopathology.

I was disappointed with the author's analysis of religions, which I found to be reliant on oversimplifications and psychological reductionism. For example, he says that "religious persons tend to be obedient, conforming, and anxious to obtain external approval" and that "believers most attracted to prayers like the 23rd Psalm are those with the greatest dependency needs."

The author misstates the conclusions of one of his citations defending his contention that certain yeshivas (Jewish seminaries) are "ultraorthodox cults" like the Unification Church and Scientology. The actual citation (1) concluded that crucial differences distinguish cults and yeshivas.

Although the author gives credit where it is due (noting that religious organizations set up soup kitchens and hospitals) and does not give all religions hard knocks (he is particularly positive about Islam), he clearly takes a wary view of religion. He suggests we come to terms with Freud's failed prophecy that religion will disappear and hopes that religions will be modified so that they can keep up the good work with "less personal cost to religious believers."

The author is troubled by the history of religious opposition to neo-Darwinism. He cites the "ominous fact" that although religion is a "great Hydra," science is a "new and possibly fragile bloom" and warns rationalists to "take note." However, neo-Darwinism has been criticized on statistical grounds by some mathematicians (2), without benefit of any theology.

The book's postulates are that 1) the psychoanalytic theory of Freud and Jung accurately describes the human condition, 2) the neo-Darwinian theory of random evolution is true, and 3) the religions of the world are complex creations of man's imagination. The number of these postulates that a reader accepts or rejects will determine whether he or she finds the book of great interest, of no interest, or somewhere in the middle.

FEAR, ANXIETY, AND COURAGE

Fear and Courage, 2nd ed., by S.J. Rachman. New York, W.H. Freeman and Co., 1990, 393 pp., \$32.95; \$17.95 (paper).

When contemplating fear and courage, I recall a tidy biographical illustration. As a small boy, Ernest Hemingway

shouted, "Fraid o' nothing," and these words, linked to his father's expectations, guided him long after he knew better (1). He was wounded as a young man fighting in Italy during World War I, and throughout his life he chased wars and danger as willingly as he chased women. He acted fearlessly even when he knew there were plenty of legitimate reasons to be afraid. Characteristically, Hemingway held a tight rein on his fears while ardently embracing courage. He valued physical courage and endurance and imposed this code on himself until, at the end, overwhelmed by alcoholism and psychotic depression, he could no longer endure and deemed it was time to die. It would be hard to imagine that Hemingway, like many others who have struggled with the contending faces of fear and courage, would not find some pithy commentary in the revised edition of *Fear and Courage*.

Not surprisingly, the bulk of this book centers on the subject of fear rather than courage. This is not unusual when we consider that the more unsettling emotions and behaviors predominate in the pages of psychiatric journals and textbooks. Even our clinical observations seldom emphasize our patients' emotional or physical strengths. It is precisely Rachman's different stance when looking at fear, fearlessness, and courage that distinguishes this book from other more traditional texts on fear and anxiety. He feels that the psychological literature on fear exaggerates human vulnerabilities at the expense of celebrating man's limitless capacity for adaptivity and acts of noble quality.

The book is divided into six sections—Fears in War, Varieties of Fear, The Acquisition of Fear, The Modification of Fear, Courage, and Conclusion. Even though the topic of courage formally occupies only a brief and final piece of this work, the themes of fearlessness and courage are interwoven throughout the text. The tone is optimistic, and since its previous edition in 1978, roughly half of the material is new and focuses on the author's broadening interests in courage, the overestimation of fear, methods of fear reduction, and the nature of panic. Original research is also described.

The book opens with a section discussing fears in war and emphasizes the unexpected emotional adaptivity of civilian populations to withstand enemy air attack. It seems that in the early days of World War II, British civilians quickly adapted and, as painlessly as possible, accommodated their daily routine to the unrelenting air attacks that came to be called the Battle of Britain. Londoners rapidly habituated to the blitz, and with a distinctly British flare for the understatement, newspaper obituaries euphemistically read, "died very suddenly."

On the morning of August 6, 1945, in an act of war without precedent, Hiroshima was instantaneously incinerated into a nuclear wasteland. Incredibly, however, the adverse psychological effects recorded among the survivors were astonishingly small, given the sweep of the devastation. Psychosis, traumatic neuroses, and other severe psychiatric disorders were reportedly rare. Within 3 months the population returned to about 140,000. (Hiroshima's population before the atomic blast was more than 300,000.)

Throughout World War II, despite steadily more fearsome raids, the urban civilians of England, Germany, and Japan became more emotionally resilient to air attack than the less threatened rural population. Among some survivors, however, fears changed to apathetic depression as they succumbed to the uncontrollability of their plight. Fearlessness seemed to hinge on the perception of control, and this was supported by the observation that fighter pilots consistently reported less fear and had fewer psychological breakdowns than bomber pilots and crews. Seemingly, their technical knowledge, self-

confidence, and sole control of their aircraft did much to lessen their fear even when confronting the catastrophically high casualty rates of their calling. This was a time when fears were not always proportional to the gravity of danger.

Anxieties and fears are defined differently, but the feelings certainly overlap. In the section entitled *Varieties of Fear*, Rachman sheds light on a puzzling array of fears and anxieties. He recognizes that fears have boundaries and often change with age and familiarity. Fear may even be simply the fear of one's own reactions; as in panic, the mind misinterprets bodily sensations. The theme of fear intertwining with anxiety disorders is further pursued in the sections *The Acquisition of Fear* and *The Modification of Fear*. The author deftly addresses the associations between agoraphobia and claustrophobia and their shared fear of entrapment. He details the limitations of conditioning theory and recommends a revised view while offering still other pathways to the acquisition of fear: vicarious experiences and the impact of threatening information. For instance, children observing frightened adults often develop similar fears. This phenomenon was observed by Anna Freud, who founded a wartime nursery in Britain and noticed that children's fears were more related to their mothers' responses to air attack than the actual bombing. Fear, like courage, can be contagious. Depending on the intent, information can generate fear or quell fear by buoying confidence. During the recent Gulf War, the Iraqi threat of chemical warfare instilled fear, but this fear was controlled by education and effective training that demonstrated survival in a chemical environment. As the author reemphasizes when discussing systematic desensitization, fears can be unlearned; generally, circumscribed fears are quickly modified or eliminated. The therapy (training) is straightforward. But what if anxiety persists long after the fearful event passes? When the signs of this spawned anxiety become intrusive, with nightmares, obsessive ruminations, and flashbacks, Rachman suggests that a fragment of the traumatizing fear remains unintegrated. He discusses this dissociation and its treatment in the chapter called "Emotional Processing."

The strength of this work is the portrayal of new findings and ideas as well as the fresh way the author views established information. The book is quite readable, the information valuable, and the price fair. However, for readers interested in the symbolism of fear and psychoanalytic clarification, this would be a disappointing read. There is a short chapter on the psychoanalytic explanations of fear with a cutting skeptical stance regarding some of the more fanciful analytical interpretations of fears and phobias. (One wonders if the author wrote this chapter tongue-in-cheek, particularly considering his views on the classical interpretations of spider and snake phobias.) This section would have been improved with a broader introduction to the author's thoughts on psychodynamic theory and the collective unconscious.

For readers interested in fearlessness and courage who relish the psychological bend, this book is an excellent starting point. Instead of lengthy commentaries on military applications or philosophical ideals, the thrust of Rachman's discussion is on training people to perform courageously, decreasing subjective fear, and reporting original research. More than likely, some readers will have a broader and more in-depth interest in bravery, and for them, *The Anatomy of Courage* (2), written by Lord Moran, a World War I battalion medical officer who later became Winston Churchill's personal physician, is the seminal work on men at war struggling against fear.

"Courage" is a word derived from the Latin *cor*, meaning "heart." It speaks to the spirit, and terms like lionhearted and

stout-hearted are synonyms for bravery. Socrates called courage a "very noble quality," and his pupil Plato ranked it with wisdom, temperance, and justice as among the cardinal components of virtue. Aristotle, not given to extremes, valued courage, placing it between cowardice and rashness (fearlessness). The emotions and behavior that range between cowardice and fearlessness are freshly examined in this book. Rachman emphasizes how competence and self-confidence can be enhanced and eventually lead to courageous actions and increased fearlessness. He contends that even the "fainthearted" are not precluded from courageous acts. He recognizes that courage, unlike fear, is a neglected topic among mental health professionals and seems to be the subject of serious discussion only among soldiers and philosophers. ("Military biographers tend to mark physical courage as the one human trait whose absence causes soldiers to fail; in few other professions is physical courage such a mandatory qualification" [3].)

Much of courage is perseverance, and Rachman is wise to embrace the continuum between fear and courage in a single text. Similarly, as Hemingway grew, he shed the phrase "Fraid o' nothing," replacing it with the quieter courage of "Il faut d'abord durer."

NEUROPHARMACOLOGY

The Neuropharmacological Basis of Reward, edited by Jeffrey M. Liebman and Steven J. Cooper. New York, Clarendon Press (Oxford University Press), 1989, 424 pp., \$75.00.

In principle, behavioral problems like drug addiction and alcoholism as well as other conditions such as eating disorders, sexual promiscuity, depression, and autism could be at least partly secondary to impaired brain reward mechanisms. Although animal models of human psychopathology seem to provide some support for this hypothesis, it is difficult to clearly demonstrate it because 1) mental disorders are more complex in humans than animal models can show, 2) reward systems in humans are poorly localized and recognized, and 3) "reinforcers" in humans are more complicated in nature (environmental, psychological) and quality (personality, social adjustment). This book is not designed to solve these problems but is devoted to answering basic neurophysiological, neuroanatomical, and neurochemical questions regarding reward mechanisms.

In the introductory first chapter, Jeffrey Liebman discusses the concept of reward and the main goals of the book:

Reinforcement shapes the interaction of higher animals, including humans, with their environment . . . Without reinforcement, the infant will not learn about the significance of other humans, the child will not heed warnings of danger . . . Reinforcement may take place

through the presentation of an appetitive stimulus or the removal of an aversive stimulus. The former instance is termed positive reinforcement and the latter negative reinforcement. This volume is concerned exclusively with the first of these instances, in which an appetitive, positive reinforcer increases the likelihood of subsequent responding. This contingency is commonly considered as an instance of reward.

In chapter 2, "Pharmacological Basis of Intracranial Self-Stimulation Reward," James Stellar and Mathew Rice deal with crucial methodological aspects of intracranial self-stimulation reward (like behavioral measurement and reward specificity) and then discuss the effects at the level of different neurotransmitter and neuromodulatory systems. A large body of evidence seems to indicate that dopaminergic systems are related to the reward produced by stimulation in the medial forebrain bundle. Stellar and Rice conclude that "whatever the exact nature of accumbens . . . [dopaminergic] functions and how they interact with reward, the importance of the accumbens to self-stimulation behavior of the medial forebrain bundle seems clear."

A further contribution to this topic comes from chapter 3, "Neuroanatomical Bases of Intracranial Self-Stimulation: Untangling the Gordian Knot." Here Anthony Phillips and Hans Fibiger discuss the complexity of demonstrating brain stimulation reward phenomena experimentally and point out the need to consider them as "subserved by many different regions of the brain rather than a unitary system located within the medial forebrain bundle."

Chapter 4, "Neuronal Bases of Intracranial Self-Stimulation" by Peter Shizgal and Beverley Murray, deals mostly with the "methods for distinguishing the directly stimulated neurons responsible for brain stimulation reward from the many other neurons that may be concurrently activated by the electrode."

In chapter 5, "Drugs as Reinforcers: Pharmacological and Behavioural Factors," Jonathan Katz reviews the literature on the reinforcing effect of different drugs such as opioids, cocaine, amphetamine, and their antagonists. Data on the possible mediating effects of dopaminergic pathways on the reinforcement by opioids are controversial: opioids could act through kappa, delta, or sigma receptors. Katz points out that the potency of dissociative anesthetics such as phencyclidine as reinforcers is closely related to their potency in displacing [³H]phencyclidine from brain membranes. He says that "there is no evidence to support the hypothesis regarding a final common dopaminergic mediation of the reinforcing effects of all abused drugs."

Chapter 6, "Neuroanatomical Substrates of Drug Self-Administration" by George Koob and Nick Goeders, deals with intravenous and intracranial self-administration of drugs. More than 20 psychotropic compounds that are self-administered by humans have been found to act as reinforcers in rats, suggesting that drug self-administration in animals may be a reliable predictor of human abuse. Of particular interest are the data showing that lesions in the nucleus accumbens can markedly decrease cocaine and amphetamine self-administration in rats. In general, the dopaminergic system seems important for indirect sympathomimetic self-administration, but systems other than the mesolimbic-mesocortical dopaminergic structures, perhaps the glutamatergic, could play a role in opioid self-administration.

In chapter 7, "Conditioned Place Preference as a Measure

of Drug Reward," Geoffrey Carr, Hans Fibiger, and Anthony Phillips show that data based on the conditioned place preference paradigm are not comparable because of different methodologies; therefore, it is impossible to draw any sound conclusions. These authors stress the need for standardization of procedures.

In chapter 8, "Central Neurotransmitter Systems and the Control of Operant Behaviour by 'Natural' Positive Reinforcers" by C.M. Bradshaw and E. Szabadi, studies involving not only catecholaminergic but also cholinergic and peptidergic pathways for the effective regulation of operant behavior by reinforcers are reported, but a satisfactory paradigm integrating these pathways in the general reinforcement paradigm is not available.

In the final chapter, "The Brain and Reward" Roy Wise states that we do not know if the unitary or multiple neural/neurochemical mechanism theory is more adequate to explain reinforcement phenomena; however, there are important proofs for the role of dopaminergic pathways (particularly of the nucleus accumbens), although other systems seem to be involved. Common physiological mechanisms could underlie all these behavioral phenomena, but there is also the possibility that "each phenomenon is independent without sharing a common final pathway in the brain."

This is a high-quality book, rich in information (sometimes controversial or overlapping) not readily available to clinicians because it is primarily directed toward basic scientists. From a clinical point of view, the biological concept of reward, although highly fascinating, is still in some way speculative, and any effort to extrapolate data from the laboratory to normal and pathological human behavior seems premature.

DREAMS

The Manifest Dream and Its Use in Therapy, by Roy M. Mendelsohn, M.D. Northvale, N.J., Jason Aronson, 1990, 256 pp., \$35.00.

In *The Interpretation of Dreams* (1), Freud took pains to distinguish the manifest from the latent content of the dream. Emphasizing his fundamental mistrust of the manifest content, he likened manifest content to the facade of an Italian church that bore no relation to the structure inside. He did so in order to argue for the point of view that the dream has a structure similar to that of the psychoneurosis and can be analyzed by using the method of association of ideas into latent content disguised by the dream work. Freud took great pains to assert that dreams should be analyzed in this way rather than being interpreted on the manifest level as allegories, symbols, or parables.

Part of this legacy of Freud's original investigations on his own and his patient's dreams has been what many analysts today would consider an excessive rejection of the manifest content of the dream as clinically useful. Not the least of the difficulties resulting from this point of view is that the dream becomes virtually unclassifiable. Federn (2) pointed to the usefulness of ego feelings in the manifest dream. In a seminal paper written in 1954, Erikson (3) pointed the way to a more balanced view of the manifest content in relation to the latent content and affirmed the overall usefulness of the manifest

dream. Since then, a good deal of clinical and empirical attention has been given to the manifest content in relation to diagnosis, in relation to clinical predicament, and in the context of the clinical course of the analysis or therapy. Although there is generally consensus that the manifest content has value, especially in conjunction with associative material and awareness of process, rather little has been written on the manifest content in relation to the process of psychoanalysis or psychotherapy.

Roy Mendelsohn's book is a big step forward in that direction. Mendelsohn has a nuanced and synthetic view of psychopathology, seeing the manifest dream as indicative of the state of cohesion of the self in relation to the type of object relationship needed to face conflicts at the libidinal and developmental level at which patients find themselves. This takes place in the context of the therapeutic or analytic process. That is to say, the day residue has very much to do with the treatment situation and the patient's unconscious perception of the therapist or analyst. Mendelsohn's many-faceted grasp of psychopathology seems to me the centerpiece of his bold attempt to argue for the value of the manifest dream in the context of the therapeutic process. Although current dynamic thinking has headed unequivocally toward considering the dream in the context of the process, Mendelsohn's awareness of processes of fragmentation and reconstitution of self-experience in relation to an object for the entire spectrum of psychopathology is both brilliant and unique.

The book, however, is not without difficulties. I found it hard to read. It is thick with theory and sometimes with idiosyncratic terminology. I found many of the numerous examples of the interpretation of the manifest dream debatable or outright unconvincing, and when I turned from the conclusion being drawn to the actual evidence supporting it, I felt sorely in need of associations to settle the matter. I am not convinced by the clinical material put forward that manifest dream material is in as close correspondence to overall psychopathology as Mendelsohn implies. He leaves the impression that the dreams of schizophrenic patients are always revelatory of schizophrenic psychopathological predicaments, the dreams of borderline patients are always revelatory of borderline psychopathological predicaments, and so forth. The bulk of the literature on the subject so far disputes this, and Mendelsohn's overriding assumption that the manifest dream is always indicative of specific psychopathology seems to me not at all substantiated by the evidence.

Despite these shortcomings, I see this as an important, bold, at times brilliant, synthesizing book that any serious student of dreams from a psychodynamic or psychoanalytic perspective will want to read.

DEPRESSION

Refractory Depression, edited by Jay D. Amsterdam. New York, Raven Press, 1991, 249 pp., \$60.00.

The pharmacotherapy and electrotherapy of major depression have had many successes and some failures. For most patients, these therapies shorten the length of individual episodes of depression or prevent or delay relapse and thus change the course of their illness. Unfortunately, a subset of patients with mood disorders develops chronic depression. Intriguingly, the proportion of depressed patients who develop refractory symptoms may not have changed since Kraepelin established that approximately 20% of his patients did not spontaneously improve. Refractory cases have become an important part of the caseload of psychiatrists because patients with straightforward depression are increasingly being treated by internists or family practitioners and only treatment-resistant cases are referred on to psychiatrists.

Refractory Depression is a collection of chapters written by many of the established experts in treating refractory or treatment-resistant depression. It meets the need for a comprehensive, in-depth compendium of data and views on the topic. The first chapter reviews the difficulties inherent in defining adequacy of a single trial and in defining treatment-resistant depression. It endorses Schatzberg's proposed model of quantifying both severity and lack of treatment response. Its most useful contribution is in citing the limitations of many existing studies. Several chapters review the hypothesized pathophysiology of affective disorder. There is some overlap among these chapters, but this is outweighed by the intriguing discussions of interactions among the various neurotransmitter and receptor systems. Clearly, no single theory has been able to integrate the existing pharmacological, neuropathological, biological marker, and imaging studies into a coherent model. It seems most likely that new discoveries will need to be made before specific pathophysiologies of the affective disorders are found.

The chapters reviewing specific therapeutic maneuvers will be of most interest to clinicians. The book has helpful reviews of lithium augmentation, carbamazepine, thyroid augmentation, stimulants, and combinations of monoamine oxidase inhibitors and tricyclic antidepressants. Also reviewed are the use of estrogen (one placebo-controlled study) and spironolactone and pemoline (no control studies for either). A chapter on depression in childhood emphasizes our lack of knowledge about the diagnosis and treatment of affective disorders in children and the need for much more research in this area. A review of stimulant drug use in the elderly will be of interest to researchers and clinicians alike. Of note in these chapters is the clear identification of areas in which knowledge is lacking and of weaknesses in existing studies.

A chapter summarizing the many clinical studies would have made a nice addition to this excellent volume. Unfortunately, there are so few studies comparing different treatment regimens that little guidance can be given to the clinician facing the thorny problem of choosing among the available treatment options.

Reprints of Book Forum reviews are not available.

Letters to the Editor

EDITOR'S NOTE: We present herewith a representative selection of the many Letters to the Editor commenting on the article about psychotherapist-patient sexual contact by Dr. Paul Appelbaum and Ms. Linda Jorgenson—a response that is by far the most vigorous and extensive the Journal has seen in many years. The authors' rejoinder to their correspondents and the related editorial by Dr. Jeremy Lazarus published elsewhere in this issue speak directly to the ethical problems that are at the center of the controversy. We should, however, like to comment briefly here on the question concerning editorial policy raised in two or three of the letters that follow.

The Editor is the doorman, not the turnkey of the Journal's gates; his task is to facilitate the admissions to its pages of papers dealing with the wide spectrum of topics and opinions that reflect the variegated interests of its readers. The constraints of space, of course, force him to make choices from among the many manuscripts submitted for possible publication, but his selection of what eventually appears in print is not influenced by pressure from those who would rather burn than broadcast ideas unpalatable to them, nor is it determined by the dictates of APA policy. Indeed, the trustees, officers, and directors of the Association have invariably been sedulous in allowing him editorial autonomy, without which the Journal would lack academic and scientific credibility. Excellence—scientific, intellectual, literary—and appropriateness for the general readership of the Journal are the primary criteria for the acceptance of manuscripts for publication, and in making his selections, however innately wrongheaded his editorial judgment, the Editor is restrained from recklessness by the wisdom and advice of the multitude of colleagues who so generously answer his requests for peer review.

The paper by Dr. Appelbaum and Ms. Jorgenson is no exception. Well versed in the practical and theoretical aspects of medical ethics, its referees praised the manuscript for the clarity of its writing and the rigor of its arguments, and despite disagreement with its basic ethical conclusions, strongly recommended its publication as a vital contribution to an important and topical professional debate—refreshing advice in an era of political correctness.

J.C.N.

Psychotherapist-Patient Sexual Contact After Termination of Treatment

SIR: While applauding the focus given to the topic of posttermination romantic and sexual relationships between therapists and their former patients by the publication of the article by Paul S. Appelbaum, M.D., and Linda Jorgenson, J.D. (1), we disagree strongly with both their conceptualization of the problem and their proposed remedies. We believe that such remedies, presented in the name of a practical solution, would, if adopted, expose patients to unnecessary risks of harm. The signatories of this letter all have extensive experience in the field of patient-therapist sexual relationships as researchers, expert evaluators and witnesses, and/or treating therapists, and these various perspectives inform our response to this article. Several of us are

distressed to find isolated portions of our own published work cited to support inferences which we believe to be mistaken and which do not reflect our writings when taken as a whole.

We disagree with the notion that such posttermination relationships simply represent one variation upon the theme of consensual sexual relationships between adults. Apart from the in-court statements of those therapists who engage in such activities, we are aware of no professional literature, either theoretical or empirical, which would support such a construction of these relationships as consensual and probably no worse than other tolerably problematic relationships between adults. Such a statement ignores what is known about the enduring effects of both transferential and nontransferential aspects of therapy, which have been demonstrated to persist for as long as a decade after termination (2–8). There are no research studies available that would support a contention that any such relationship begun more than 1 year after termination would not entail risks of harm to patients.

We also challenge the conclusion that a 1-year waiting period would be a sufficient rein on such relationships and would serve to prevent most foreseeable harm. Dr. Appelbaum and Ms. Jorgenson cited data, essentially drawn from studies that did not have posttermination relationships as their primary focus (2, 3), that seem to indicate that a majority of such relationships reported in these studies became overtly or genitally sexual within 6 months of the official termination of therapy. They interpreted this to mean that these relationships were the result of a "hasty infatuation" on the part of the therapist and/or patient that would fade over time if a 1-year waiting period were put into place as they suggested. They suggested that a 1-year ban would be practical, since it provides a clear time period to a therapist wishing to propose such a relationship, and at the same time would purport to protect patients by giving them time to consider.

Our experience indicates otherwise. This brief latency between official termination and initiation of overt sexual relationships is indicative of the nonconsensual, transferential nature of the relationship.

Dr. Appelbaum and Ms. Jorgenson disregarded the risks present in offering to either therapist or patient an official time at which overt sexual contact may commence (4–7, 9, 10). When the possibility of a sexual relationship exists in the mind of either party, but particularly that of the therapist, psychotherapy can and all too often *does* become a courtship, a process of grooming in which a vulnerable individual is shaped to meet the sexual and narcissistic needs of the therapist. Therapy in such a case ceases to be in the interest of the patient's growth and may take paths which are antithetical to her or his well-being when the goal of becoming a sexual or romantic partner of the therapist becomes a predominant one.

If this grooming, which is inevitably countertherapeutic, includes the imposition of a 1-year waiting period, we fail to see how this prevents harm or avoids the intrusion of the therapist's sexual and narcissistic needs into the field of psychotherapy. A 1-year posttermination rule for sexual relationships between therapist and patient may lead to more premature terminations of treatment; it may make the relationship more

valued, and less questioned and reflected upon, because of the obstacles of time and separation placed upon it. We are all aware of cognitive dissonance theory which suggests that the higher the price, the more valued the choice and the less likely that it will be critically reflected upon. Dr. Appelbaum and Ms. Jorgenson err in suggesting that our professions reward those individuals with better impulse control and ability to delay gratification and ignore the meaning of their activities.

Dr. Appelbaum and Ms. Jorgenson emphasized that few appellate cases involving posttermination sex have been reported, implying that this may be much ado about nothing. However, the number of appellate cases may be an unreliable, biased, and unrepresentative guide to the relative frequency of either the number of civil cases filed in the instance of a posttermination relationship or the number of such relationships per se. In fact, in our collective experiences, such cases are becoming one of the common varieties of sex between therapist and patient (4, 10). Many cases are settled before trial and thus would not be appealed. Most cases never enter the complaint process at all.

Dr. Appelbaum and Ms. Jorgenson also argued that there is no strong evidence for harm as a result of such relationships. While we would agree that the published literature is short on such information, and consider ourselves partly responsible for not having collected and published the information we have gathered in the course of our clinical work, our impressions are otherwise. That is, we have seen the same type and severity of harm devolving from posttermination relationships as from those initiated by therapists with less effective impulse control (10). The one available empirical study (4) does indicate that subsequent therapists were able to identify evidence of harm to clients in approximately 80% of such cases of posttermination relationships; this cannot be seen as an insignificant number. There is also no evidence at all to suggest that posttermination relationships, whenever they commence, do not cause harm.

We do not believe that it is justified, clinically or ethically, for a therapist to engage in sexual intimacy with a patient or former patient, regardless of the amount of time that has elapsed between termination and the sexual intimacy. However practical a 1-year rule might be, it would be improper to allow questions of practicality to override those of ethics and concern for the welfare of vulnerable individuals. There is no reason why therapists should take such risks with the well-being of anyone whom they have encountered in the course of a doctor/therapist-patient relationship given the magnitude of the harm that can and often does occur. To establish an arbitrary 1-year waiting period ignores the dynamics of the therapeutic relationship and the long-lasting effects of those dynamics, while it carries the implicit message that such relationships are permissible. This will encourage abuses which can only create added risks of harm for patients.

SIR: As a victim of sexual misconduct by a physician/therapist, I read with great interest the article by Dr. Appelbaum and Ms. Jorgenson.

From my association with other victims and experience with caring mental health care professionals, I have heard a resounding "It's never OK" to have a romantic/sexual relationship after therapy is terminated because of the dynamics that have been created and the inequity of the situation. Why then do I believe that there is some merit in a posttermination waiting period?

First, most cases of sexual misconduct and abuse take place during the therapy hour. A posttermination period would not apply to these cases. Second, while I am in 100% agreement, in principle, with the "It's never OK" stance, I feel that this absolute position provides no direction out of a hot situation that may be perceived (by both involved) as true love.

Therapy is not a place that should provide dating opportunities for single therapists, yet I have heard too often in presentations by some professionals in the community the advice that if you fall in love, simply terminate, refer the patient, and then see the individual.

Would a therapist voluntarily wait to begin what may be viewed as just a romantic relationship? Does the victim, who

views the therapist in many cases as the only person who can lead the way out of a painful life situation, understand the dynamics of the patient/therapist relationship at the time of a hasty termination? What would a waiting period provide in these cases?

A posttermination waiting period, with no contact between the patient and the therapist, would set forth guidance for both parties. During the waiting period each party would need to undergo independent therapy to sort out feelings of transference, "love," the power differentiation, dependency, and, for the patient, the reason he or she came into therapy in the first place.

The waiting period would set a standard and provide a cool-off period and an opportunity for the patient to learn about therapy dynamics and about the therapist's potential for power and control during a period of patient vulnerability. It could move the relationship out of secrecy into open discussion. It could provide the opportunity for community involvement and accountability.

"It's never OK" may be, in principle, no more than a terrific bumper sticker slogan. The "never" position fails to provide guidelines and leaves unresolved feelings. It may also lead to temptation and sexual contact with, most often, damaging results to both the victim and the physician. My hope is that a posttermination waiting period could be supportive to both parties and may result in a continued no-contact arrangement.

DIANE D. ARONSON
Arlington, Mass.

SIR: Dr. Appelbaum, Ms. Jorgenson, and the *Journal* are to be congratulated for stimulating the vigorous national debate which has followed the publication of their article.

Studies of the beliefs of professionals as to the ethicality of posttermination sex between a therapist and former patient have found that only 50%–60% rate such behavior as never ethical (1, 2). In one study sex with former patients was rated virtually identically to "inviting clients to a social event" and "telling a client of your sexual attraction to them" (1). In discussions with hundreds of professionals over the past 20 years we have found virtual agreement on only one issue: that terminating in order to have sex is unethical.

In our own work, which involves consultation in several thousand cases of therapist-client sex, the vast majority of complaints of posttermination exploitation come in situations where there has not really been a termination or in which there was a "quickie termination" to justify sex. Cases where therapist and client have *no contact* for, say 1 year, are extremely rare, and we often hear about them indirectly—not as a result of a grievance (3).

The few studies cited concerning the long-term persistence of transference (4), focus on long-term dynamic therapy or psychoanalysis. None have examined whether the therapist still has power over the client and whether a sexual relationship would be exploitive. Furthermore, we lack any research on the posttermination situation with briefer therapies, consultations, etc. If one is concerned about undue influence or exploitation, it would seem that developing a friendship or financial relationship would be just as worrisome, although only 14.7% of therapists rated this as "never ethical" (2). As Dr. Appelbaum and Ms. Jorgenson noted, one study even found 29.6% of therapists rating marriage with a former patient acceptable after proper termination of long-term therapy.

Regarding marriage to former patients, do we denigrate or declare such relationships as *a priori* exploitive? If so, what

about the children who result, some of whom also enter our field as therapists? We obviously need more clearly articulated standards, and the solution proposed by some, "It's never OK," doesn't help any more than the current, "It's nearly never OK." Any such standard needs to include 1) a clear definition of termination; 2) a posttermination time interval, which, as Dr. Appelbaum and Ms. Jorgenson noted, must exclude any contact; and 3) that additional criteria beyond the waiting period be defined. Our own work (3) analyzes these issues in greater detail and recommends: 1) a prohibition against sex with former clients of long-term, transference-laden therapies; 2) a 2-year waiting period; and 3) a prohibition against sex with former clients who have special vulnerability due to past victimization.

Once standards are established, we must deal with informed consent. What must clients be told about all of this upon entering therapy? Finally, since the vast majority of cases which led to complaints, or where harm appears to have occurred, involved liaisons within 6 months of termination, our focus needs to be on the major problem: the phony termination or the quickie termination.

GARY SCHOENER
Minneapolis, Minn.

SIR: Dr. Appelbaum and Ms. Jorgenson have provided a comprehensive and thoughtful review of the legal basis for sanctions of posttermination sexual activity between psychotherapist and patient. They are correct that an absolute lifelong ban on sexual activity would probably not withstand legal challenge and that a 1-year prohibition after termination is a reasonable, justifiable, and enforceable limit. It is important to make the issue more clear, as disciplinary bodies have not had clear guidelines to follow.

Lifetime prohibition of sexual activity is problematic ethically as well as legally. Respect for autonomy is a primary ethical mandate, and it is hard to defend the proposition that a patient can never make an autonomous choice to enter into a sexual relationship with a former therapist. The question of patient autonomy is a difficult one in psychiatry, but certainly we do not want to insist that the act of becoming a patient removes a patient's autonomy for life, even in a limited arena. After all, if returning the patient to autonomy is not the goal of psychotherapy, what is?

We applaud the efforts of Dr. Appelbaum and Ms. Jorgenson to settle on a proposal for an ethical and legal standard that makes clinical sense.

KAREN RITCHIE, M.D.
RAY HAYS, PH.D., J.D.
Houston, Tex.

SIR: Dr. Appelbaum and Ms. Jorgenson have done a great service by frankly addressing the much gossiped about, but woefully neglected, topic of doctor-patient posttermination sexual involvement. I was, however, disturbed by their failure to discuss sufficiently two main points.

First, while there was substantial exploration of the various issues involved and a pragmatic solution of a 1-year grace period after termination was offered, there was, in my opinion, a lack of appropriate outrage at the basic situation. Why are doctors not being urged to examine seriously their motives, countertransference and otherwise, through personal reflection or resumption of their own treatment for such involvement with their (former) patients? While doctor-patient romantic and sexual liaisons have happened historically and are perhaps occurring now in larger numbers, this should not mitigate our concern and calls for serious self-examination each and every time such a transgression happens.

Second, the authors barely discussed the gender breakdown of such doctor-patient pairings and only commented that they nearly always tend to be male doctor-female patient. It is important to know whether female psychiatrists enter into sexual relationships with their patients—in what numbers and under what circumstances. It would be very interesting to compare such data with those gleaned from male colleagues and to explore similarities and differences.

MICHELLE E. FRIEDMAN, M.D.
New York, N.Y.

SIR: As a former Chairman of the Committee on Ethics of the American Psychoanalytic Association and former Editor of the journal *Psychiatry*, I was shocked and dismayed by the recent article of Dr. Appelbaum and Ms. Jorgenson. It is wrongheaded, reckless, and mischievously harmful.

In their discussion of why posttermination therapist-patient sexual contact is "undesirable," the authors omitted almost entirely the damage to the treatment process from violation of the principle of abstinence. They failed to recognize that the purpose of abstinence in treatment is to enable the patient to remember and come to terms with the past pain of refused and lost love and to resist the temptation to give way to a short-cut, magic elixir "love cure."

The promise of future gratification inherent in the idea of a socially sanctioned "waiting period" makes a mockery of the principle of abstinence, of professional ethics, and of the integrity of the treatment relationship, to say nothing of evoking associations to setting waiting periods for handgun purchase or for going through the revolving door from government service to influence peddling.

The authors attempted to support their proposal with casuistic reasoning and slanted, selective use of available data. They asserted that "treatment and the obligations it places on the therapist are time limited" and that "for most purposes the fiduciary relationship ends when therapy is concluded." On the question of how long and in what forms transference persists, they argued that for most patients it diminishes with time, but in actuality the psychoanalytic studies by Pfeffer and by Norman et al., which they cited in support of their argument, give strong evidence of how powerful and easily revived transference effects are and how important enduring elements of identification with the therapist's mode of addressing and solving problems are to the patient's future functioning. The authors selectively omitted these observations. Although they acknowledged weakly that "some data suggest that some patients may retain feelings about their therapists for considerable . . . time," they immediately added the further weakening qualifier, "It is unclear whether

these feelings are of the type or magnitude which would interfere with competent decision making."

We can anticipate rapid consequences from the proposal: it will be popular with many, a number of treatment terminations will be hastened, it soon will be suggested that a 6-month wait may suffice, and defendants and their attorneys in ethics and malpractice cases will eagerly seize upon this article for their defense.

These are but a few of my objections. In addition, the acceptance and positioning of this as the lead article raise serious questions about referee and, I regret to say, editorial judgment. At most, it may belong on an op-ed page, but not in a scientific journal, despite its cloak of scientific form. Its coincidental publication at the same time as PBS's "Frontline" airing of "My Doctor, My Lover" is further cause for dismay.

DONALD L. BURNHAM, M.D.
Bethesda, Md.

SIR: I read with considerable interest and eventual consternation the most provocative article by Dr. Appelbaum and Ms. Jorgenson on psychotherapist-patient sexual contact after termination of treatment. I believe that their proposal has the potential of setting a most dangerous precedent that could result in highly manipulative and nonprofessional behavior in those psychotherapists so predisposed. Indeed, I could foresee the entire therapeutic relationship in some instances totally manipulated by the unscrupulous therapist to fulfill his or her own personal needs.

In making their recommendations, Dr. Appelbaum and Ms. Jorgenson are assuming that our work with patients in psychotherapy is of a finite nature, in that there is a clearly demarcated endpoint. However, given the chronicity of the majority of the disorders that we treat (e.g., severe anxiety-based disorders, major depression, personality disorders, schizophrenia), the high recidivism rates, and as I have pointed out elsewhere (1), the importance of providing booster treatment over extended periods of time after discharge, it is not uncommon for patients to return for retreatment or less intense booster treatment even several years after termination. That being the case, even given the 1-year hiatus in contact between the therapist and patient, I am not convinced that the patient will be able to make an informed and unbiased judgment about entering into a personal relationship with a prior therapist. Indeed, even 1 year or more after termination, the patient's status in relation to the therapist will be of a subservient nature. I agree with Herman et al. (2) and Gabbard and Pope (3) that sexual intimacy between the therapist and patient is tantamount to a breach of the incest taboo. I can see no circumstances under which this taboo can be rescinded. As to Dr. Appelbaum and Ms. Jorgenson's proposal, I say, caveat emptor!

MICHEL HERSEN, PH.D.
Pittsburgh, Pa.

SIR: It is timely that Dr. Appelbaum and Ms. Jorgenson addressed the issue of posttermination sex during the current national debate on what behavior constitutes sexual exploitation. This is an important but neglected issue and the authors should be praised for addressing it directly. Nevertheless, I believe they reached the wrong conclusions and wish to make the following points.

The authors argued forcefully and correctly that sex during therapy is likely to be harmful to the patient, but went on to state that the reasons for preventing sexual contact are "weaker" for sexual relationships after termination. Although the reasons may be "weaker," that does not mean they are insufficient. Consider the case of a person who maintains some transference feelings after termination that lead to impaired decision making. That person might wish to become involved with an idealized authority figure to defend against inner distress. Our purpose in working with patients is to help them to become more satisfied with themselves and more empowered in their lives, not to help them attach themselves to an idealized authority figure. Since the authors acknowledge the lack of useful data about posttermination sex, shouldn't we be cautious and try to prevent potentially unhealthy behavior by patients?

The authors' argument that posttermination sex could legitimately occur 1 year after termination assumes that therapists are well-meaning, but there are therapists who are malevolent and whose own gratification is their primary concern. What a boon to a predator (and our profession has them) to have a rule explicitly allowing sex with any patient whom one hasn't seen for a year!

The authors' concern that rules forbidding posttermination sex are unconstitutional is primarily a legal one. We should not use legal reasoning to make decisions about what is good patient care when that reasoning requires a thorough understanding of issues outside our area of expertise. Even Supreme Court Justices disagree on what behavior is constitutionally protected. We and our patients are better served if we articulate our patients' complex needs and vulnerabilities, such as posttermination feelings and wishes, and help the legal profession to use their conceptions to serve those needs.

The authors' main argument against a total ban on posttermination sex is that it would preclude "relationships that may involve no more problems than many relationships routinely sanctioned in our society." That society has sanctioned relationships in which power is easily abused is not justification for our sanctioning a relationship that could easily include exploitation as a component. Given our rather dismal behavior in the past in advocating for chronically ill and sexually abused patients, it is perhaps too much to hope that we could take the lead to oppose exploitation, but it would certainly be a step in the right direction for psychiatric organizations not to condone it.

There is a significant potential for harm to a patient in a sexual relationship with a former psychiatrist, and this goes against our primary ethical responsibility as physicians to "first do no harm."

EDWARD H. DRUMMOND, M.D.
Portsmouth, N.H.

SIR: The assumption of Dr. Appelbaum and Ms. Jorgenson, that residual transference from prior treatment interferes with ex-patients' competent decision making concerning sexual behavior with previous therapists, stands in interesting contrast to another article, published contemporaneously by an equally erudite scholar, Professor Slovenko (1). In his article Slovenko stated, "In truth, transference jargon has beclouded common sense."

Transference as a basis for implying aberrant ethics, disgraceful behavior, or even, in some states, crime when it involves posttermination therapist-patient sex represents an absurdity worthy of analysis. Let's face it: all people retain positive or negative residual transferences toward important persons represented during their formative years, most commonly their parents. One would hardly cite residual child-parent transference as decision impairing and as a coercive influence in the case of an adult of average intelligence failing to exercise judgment independent of parental wishes. The capacity for decision making in nonpsychotic and intellectually normal people totally outweighs the assumed mythical power of transference.

What about transferences that develop during the course of group therapy? If society is going to hold psychotherapists liable for posttreatment sexual involvement with former patients, then the next pseudological step would be to hold therapists responsible for transferences that develop between group members in therapy and that escalate into undesirable sexual involvement when the therapy is terminated. Such an argument would conceivably hold a therapist liable for previously exposing ex-patients to transferences with other patients as a result of which, subsequently, the capacity to refuse sex with the transferee is psychologically impaired.

To state that sex with former patients is by and large professionally undesirable is an issue quite separate from blaming impaired decision-making capacity because of residual transference. Such a hypothesis reinforces an unfortunate trend in our society, namely, overemphasis upon vulnerability of, and compensation for, potential victims and underemphasis upon the moral value of doing right instead of wrong.

THEODORE PEARLMAN, M.D.
Houston, Tex.

SIR: In their article, Dr. Appelbaum and Ms. Jorgenson argued that a sexual relationship between a psychotherapist and former patient is permissible after a 1-year waiting period. I suggest that if the therapist and patient are to engage in intensive psychodynamic psychotherapy, a better rule from the start is that there should never be such a relationship. This prohibition is inflexible, but not needlessly so, and is based on a fundamental view of the nature of intensive psychodynamic therapy and its effect on both members of the dyad.

It is a well-known view that unconscious wishes are timeless and that such fantasies exist unchanged over the years after they first occur. Thus, the wishes which are a part of the child's oedipal constellation are always there, available to emerge in different conscious, derivative forms. Wishes that an adult develops and that are considered dangerous are subject to repression and remain unconscious, but unmodified. Romantic and sexual feelings a therapist feels for a patient could be repressed in this context if the therapist considered them potentially dangerous.

There is also a growing literature that suggests that transferences are an ubiquitous part of everyone's life experience, are probably a way of providing a framework for cognition and perception, are rooted in each person's biopsychosocial endowment and history, and are an important part of many therapists' experiences with many patients with whom there is a deeply probing dynamic relationship (1). To know the patient, the therapist will experience transferences toward the

patient and thus experience intense feelings based not only on his or her consciously known past and present but also on the basis of his or her unconscious past actual and fantasized experiences. Further, some therapists unconsciously identify with their patients (2) or the individuals their patients describe in the therapeutic transference (3). This seems to be a special form of transference, involves the therapist's subconscious past experiences as models, and is experienced by those therapists who allow themselves to be carried more fully into their patients' intrapsychic worlds. This is an essential way for these therapists to learn about their patients, because parallel processes of self-discovery can then occur (2).

Thus, in the crucible of the intensive psychodynamic therapeutic relationship, very strong feelings will be stirred in the therapist as well as the patient. Given the old views I describe about the timelessness of unconscious wishes and the newer ones about the therapist's transferences, identifications, and ways of knowing, it seems prudent for the therapist to afford himself or herself and the patient the insurance of a fail-safe caveat: romantic and sexual fantasies are necessary and proper in the minds of both parties, if such fantasies are a way of understanding the patient's conflicts, but are never permissible in action. Only then can the therapist avoid repression of his or her feelings about the patient, which might prevent understanding the patient during the therapy and/or permit actualization of a previously unconscious wish of the therapist's after termination. Only then will both therapist and patient enjoy the freedom to explore the patient's psychological world in the greatest possible depth.

STEPHEN M. SONNENBERG, M.D.
Washington, D.C.

SIR: The thoughts that follow are in disagreement with the recent article by Dr. Appelbaum and Ms. Jorgenson. Since I can write only as a psychiatrist, I am addressing only clinical and associated ethical aspects of the article and not its possible legal usefulness.

I think the authors significantly downplayed the endurance of transference and the intensity of its grip even after many years after termination. What the authors seem to be mistaking for a withering away of the transference is more a diminution of the place of transference derivatives in the consciousness of the (former) patient. We really have little reason to believe that the potential for exploitation diminishes nearly so rapidly or even so much over time as the authors seem to think. Further, the potential for the transference to impair decision making by the former patient, and for the lingering countertransference to impair decision making by the former doctor, is similarly long-lived, most especially for matters of great personal emotional import in their relationship to each other. I think the authors' viewpoint is a kind of new edition of an older view, once current in psychoanalytic circles, that adequate interpretation of the transference in the course of treatment actually succeeds in abolishing it. We have, over the decades, learned the hard way that this is not so. The authors now seem to suggest that even if transference is not abolished (or hugely lessened) in the course of treatment, then the pas-

sage of a year without contact with the doctor will finish the job, so to speak. I think this is most naive.

I could foresee a nightmare for any District Branch ethics committee in the event of a filed complaint, trying to decide 1) if a year had in fact passed since the end of treatment, 2) if no significant social contact had occurred during the year, i.e., deciding whether whatever contact occurred, if any, crossed the line, and 3) whether or not, in a given case, one of the various exceptions admitted to by the authors should mandate a permanent proscription of posttermination sexual contact.

There would remain, if we followed Dr. Appelbaum and Ms. Jorgenson's recommendation, the difficult problem of the consenting posttermination patient who, after a (posttermination) affair or even marriage with the former psychiatrist, came to understand that actually residual transference issues had led to the consent. Now we know that transference is an important element in all relationships, including love relationships. In the event of a posttermination marriage or affair turned sour, it would be a particularly daunting task for any ethics committee to attempt to sort out which transference issues derived from the period of treatment and which (if any) did not.

While I agree with the authors about the problems they cited as resulting from our current "almost always is unethical" characterization of posttermination sex, I cannot agree with their solution and would prefer a flat-footed statement that posttermination sexual contact "is unethical."

Of course there would be some abridgment of freedom resulting from a permanent ban on posttermination sexual contact and conceivably a (rare) suitable and nonexploitative relationship would be frustrated. But there is every reason to believe that the cost it would impose would be very greatly outweighed by the grief and mischief such a ban might help prevent.

PAUL E. SAPIR, M.D.
Providence, R.I.

SIR: I read with interest the article by Dr. Appelbaum and Ms. Jorgenson. I differ, however, with their proposal that sexual contact between a therapist and ex-patient be permissible 1 year after therapy has terminated provided certain conditions are met. On the basis of my own clinical experience, I believe that a therapist should never have sex with an ex-patient. Let me illustrate with a brief case history.

Ms. A was a young woman who began twice weekly therapy with a male therapist because of depression and inability to function as an expert in her field. After several years, she overcame her depression and returned to full functioning in her field. Therapy was then terminated to the patient's and therapist's satisfaction.

After termination she saw her therapist at large social gatherings involving mutual acquaintances once each year. At one of these gatherings, 15 years after termination, she had sexual relations with the ex-therapist. This sexual experience was a disaster for the patient. She felt that the therapy had been a fraud. The patient was able to function only in a narrowly circumscribed area as an expert in her field. Otherwise she was miserable and depressed.

After numerous attempts at treatment, she started therapy with me. The rage and suffering expressed by the patient were so intense that she was convinced that she was nearly psychotic, although objectively she was not. Fortunately, in this psychoanalytically oriented psychotherapy,

three times weekly over many years, severe anxiety and conflicts reactivated by the sexual liaison with her ex-therapist were worked through sufficiently for a successful termination. What finally emerged in treatment was the lifting of repression of her sexual experiences with a beloved relative when the patient was 4 years old.

The patient herself was able to see that what had occurred during the first therapy was a transient transference "cure." She understood that she was driven to repeat her past with her kindly relative, personified by her first therapist in the transference. This drive to repeat the past was not consciously known to either the patient or the ex-therapist at the time of the sexual contact.

Transference "cures" like this case are probably commonplace. The therapists and patients are often totally uninformed about repressed psychological issues of both a sexual and an aggressive nature. Even in psychoanalysis, the transference can never be completely resolved. Therefore, it would appear prudent not to take a chance with an ex-patient's psychological health for the ex-therapist's sexual gratification.

In my opinion, there is always a risk of seriously traumatizing an ex-patient if there is posttermination sexual contact with an ex-therapist, no matter how long after therapy has ended. For that reason alone, a therapist should never have sex with his ex-patient.

ALVIN CURTIS SPINDLER, M.D.
Ann Arbor, Mich.

SIR: Dr. Appelbaum and Ms. Jorgenson have written a useful analysis of a major professional problem, the sexualization of the therapeutic relationship after treatment termination. They differentiated criminal law, civil law, common law, administrative boards, and professional societies as they related to this issue. They then implied that their proposal of a "1-year waiting period after termination" would fit the regulatory needs of all agencies.

It would have been more helpful, I believe, if they had stayed with their differentiation. Regulatory agencies, legislatures, and APA have quite different functions, and the "appropriate" position of each will probably not be identical.

While psychiatrists, through APA, are influential consultants to legislatures and regulatory bodies, we alone are fully accountable for controlling our own internal standards of professional ethics. These standards not only help us avoid abusing current and "former" patients but they also help us take care of future patients by creating an ambience that fosters professional pride and public trust and confidence. The therapist's office must be uncommonly safe.

In answering patients' questions about the fee and time structure, confidentiality, and other frame issues in our work, would we feel comfortable with "after termination of the treatment, it is professionally ethical for us to have an intimate social relationship if we both wait 1 year"?

In these times when we are working to improve the public image of psychiatry, who would be harmed by our professional society taking an ethical position that, for purposes of our own, stated, "Once a patient, always a patient"?

THEODORE I. ANDERSON, M.D.
Lexington, Mass.

SIR: Neither Hamlet nor a worried patient will find comfort in Dr. Appelbaum and Ms. Jorgenson's "proposal" that therapists slow their "wicked speed, to post with such dexterity to

incestuous sheets!" by waiting 12 months before having sex with their former patients. Neither the passage of time nor the imprimatur of the wisest consultant can undo the incestuousness of such liaisons.

The authors miss the point. If the "too, too, solid flesh" is actually weak and likely to melt, then the architecture of the therapeutic contract must be strong. Patients and therapists need to know, from the moment treatment makes them vulnerable to their transferences and countertransferences, that the nature of the professional relationship will always remain inviolate. Treatment requires the safety of such a frame. Its anticipated future violability would destroy the therapeutic frame retroactively throughout the course of a treatment.

After all, what forbearance is demanded of psychiatrists? Out of several billion potential partners available for intimate relationships, a hundred or so shall be irrevocably excluded from consideration, in exchange for a good livelihood, an honorable profession, and the (different) gratification of a professionally bound relationship. Is this really a sacrifice before which the profession must quake and tremble?

The article will justifiably frighten many patients, especially those with memories of traumatic violation in their past who already fear for their safety in psychiatric treatment. They will be troubled by psychiatrists' reluctance to be bound by the rules that define the framework of their efficacy. Publishing this article without disclaimer in the *Journal* was a serious error in editorial judgment. "It is not nor it cannot come to good."

PAUL HAMBURG, M.D.
Boston, Mass.

SIR: The scholarly article by Dr. Appelbaum and Ms. Jorgenson sharpens the focus on the pressing ethical problem of psychotherapist-patient sexual contact. At the same time it fails to take account of two basic issues. One of these is the incontrovertible fact that no two persons absolutely *must* achieve sexual connection. Strong desire, even a sense of compulsion, may exist, but the consummation is not a human necessity. That being said, the issue of fiduciary responsibility requires reexamination. The psychotherapist-patient relationship, if not unique, is at least on an order of magnitude more intense than the more general doctor-patient one. The mindset of the patient that endows her or his therapist with special qualities may soften with time, but it does not go away. Posttherapy contact inevitably capitalizes on that fact, whether in a week, a year, or a decade. In that sense, it is inevitably exploitative, varying only in degree. Sexual gratification of the therapist is achieved through exploitation—period! My second point is that the authors' proposal of a 1-year mandatory "waiting period" contains within it a truth that they have not acknowledged. That is the fact that the protagonists are waiting. They are waiting to fulfill a possibly unspoken contract entered into, whether in or out of their awareness, during the course of therapy. The observation that only 1% of cases of posttherapy sexual contact coming to adjudication began after 1 year is beside the point. The potential for harm to the patient is the point. But the therapist is also harmed, by blunting his or her ethical sensibility.

It should be cause for embarrassment that the Florida Board of Psychologists has adopted a higher standard of conduct than we psychiatrists have: the acknowledgment that the psychologist-client relationship is deemed to continue "in perpetuity." In summary 1) we do not have to have that sexual relationship and 2) a codified "waiting period" institutionalizes abuse of a continuing fiduciary relationship. I applaud the proposal of a uniform rule applying to "all treatment provided

by psychiatrists and nonmedical psychotherapists." Let it take these issues into account.

GEORGE E. MURPHY, M.D.
St. Louis, Mo.

SIR: Dr. Appelbaum and Ms. Jorgenson presented an interesting and controversial proposal regarding psychotherapist-patient sexual contact after termination of treatment that attempts to be both sensitive to the issues and simple to apply. I have concerns, however, about the narrowness of their focus and the implicit assumption that psychiatrists should be lumped with nonmedical psychotherapists rather than with their medical colleagues. While the authors noted that psychiatrists engage in a variety of relationships with patients, ultimately they made the assumption that all psychiatrists are defined, for their purposes, as psychotherapists. They feel that it is impossible to distinguish when the relationship crosses the line from a more "medical" role into a psychotherapeutic one. While unable to distinguish a line between psychiatrists and psychotherapists, they have, in fact, established an arbitrary boundary between psychiatrists and other physicians.

Clearly, the appropriate boundaries of the complex relationship between individuals and their psychotherapists need to be considered with extreme care. At the same time, however, this is an issue which should also be specifically addressed in other professional settings. On what basis have the authors excluded nonpsychiatric physicians (or for that matter, other professionals, such as lawyers) from their proposal? The factors associated with societal limitations on individual choice, i.e., impaired decision-making capacity, coercion, and fraudulent representation, can all apply to other professional relationships with similar "power imbalances" (for example, gynecologists and their patients, bankers and loan applicants). While transference issues are obviously most pertinent to the psychotherapeutic relationship, it is a phenomenon implicit in all human relationships. I would be interested in where and how the authors would apply these or similar guidelines to other professional groups.

HAROLD ALAN PINCUS, M.D.
Chevy Chase, Md.

SIR: I read with interest Dr. Appelbaum and Ms. Jorgenson's recent article. I am not sure what the best time interval should be before posttermination patient-therapist sex might be legally permitted, although I think the effect of transference is frequently much longer than the authors imply.

An important side effect of the increasing societal penalties for therapist violation of the sexual taboo with patients is that what used to be a matter of integrity or pride for the appropriately abstinent therapist is now becoming only a matter of coercion for the scoundrel. We have all lost something when our behavior as therapists is increasingly regulated.

JOEL KOTIN, M.D.
Laguna Beach, Calif.

SIR: It is an unfortunate reflection of the preoccupation of our society with genital activities that Dr. Appelbaum and Ms. Jorgenson, in their otherwise superbly thoughtful review, should fail to consider the most common setting for sexual contact in our society: marriage.

The authors noted that the specific elements providing the basis for restricting therapist-patient sexual contact—the pa-

tient's impaired decision-making capacity, the power differential favoring the therapist, and the likely dishonesty, covert or overt, in the situation—while perhaps no less commonly found in ordinary sexual encounters, provide a valid basis for such restrictions in therapist-patient encounters because of "the unfairness of allowing the psychotherapist to benefit from the patient's compromised decision process while the patient risks substantial harm." Although it might be argued that while nonmarital sexual contact between therapist and patient, as a purely private behavior, insofar as it does not afford a remedy to an injured or exploited party, warrants anticipatory supervision to prevent injury or exploitation where the risk is predominately one-sided, marriage, where both parties are at risk, does not require such supervision, since divorce laws provide a remedy for the injured party should the relationship fail.

I suggest that this is a specious argument. Abusive, exploitative marriages in our society are hardly uncommon. They are often held together by the very pathological interactions that brought them together (until they fall apart when one of the parties has been so damaged by that interaction as to be unable to continue). This is rather late for providing a remedy, especially when the parties were originally brought together in the societally structured therapist-patient encounter, and as Fitzgerald painfully portrayed in *Tender Is the Night*, when the parties are psychiatrist and patient, the victim is not necessarily the patient.

The proposal advanced by Dr. Appelbaum and Ms. Jorgenson is well reasoned and based on data, however limited, rather than on abstract theoretical formulations. I suggest that it be clearly extended to include posttermination therapist-patient marriage, even in the absence of premarital sexual contact.

SIMON L. AUSTER, M.D., J.D.
Bethesda, Md.

SIR: I found the recently published proposal by Dr. Appelbaum and Ms. Jorgenson on psychotherapist-patient sexual contact after termination of treatment to be of interest, but to be unsupported by the analysis which the authors provided. I would question the rationale which they put forward to support their proposal.

The argument for the 1-year waiting period is to allow transference issues to diminish, to avoid coercive influences, and to allow adequate time for the therapist to reflect on the desirability of the proposed involvement. The authors went on to note that if this 1-year period of abstinence is observed, a sexual relationship is seldom initiated. Their own experience described only one case out of more than 100 where such contact between a therapist and a former patient began more than 1 year after the termination of treatment. They then cited the Minneapolis experience where again fewer than 1% of cases of therapist-patient sexual contact began more than 1 year after termination. This seems to me very strong evidence that "appropriate" therapist-patient sexual contact after termination of therapy occurs only rarely.

It would seem that the authors are going to great lengths to justify a behavior that occurs less than 1% of the time. Ninety-nine percent of the time sexual contact occurs less than 1 year from the termination of therapy and is inappropriate by the authors' standards. And even in the 1% that does occur after the 1-year period, there is no assurance that all of the issues of concern that have been raised regarding lingering transference issues, coercive elements, etc. are resolved. In addition we have the very real concerns that Gabbard has so clearly spoken to regarding the contamination of therapy by the

knowledge that such a relationship could be possible in the future. It seems unjustified to contaminate so many ongoing therapeutic relationships with this possibility, particularly when an outright prohibition will be the appropriate position in more than 99% of the cases.

With such a relationship being so rarely appropriate, I prefer to see our profession strongly support the rule rather than the rare exception. In my opinion the APA's position that "sexual involvement with one's former patient is . . . almost always unethical" remains the appropriate stance.

STEWART SHEVITZ, M.D.
Eugene, Ore.

SIR: I write to express concern over the apparent erosion of the editorial independence of the *Journal*. As reported in *Psychiatric News* (1), a recent article by Dr. Appelbaum and Ms. Jorgenson (2) caused considerable controversy within the profession. Also according to *Psychiatric News* (1), the Editor of the *Journal* acquiesced to pressure from the APA Board of Trustees to allow a belated editorial response to the article from the Chair of the APA Ethics Committee.

Although I fully support open debate and discussion of controversial issues and opinions published in the *Journal*, I am concerned that undue influence from the Board or other groups within APA will actually diminish the editorial independence and scientific integrity of the publication.

The article by Dr. Appelbaum and Ms. Jorgenson was reviewed and accepted through the established blind peer review process. Decisions regarding subsequent discussion and debate of this or any other article published in the *Journal* should be left entirely to the discretion of the Editor and editorial review board.

DAVID FASSLER, M.D.
Burlington, Vt.

Dr. Appelbaum and Ms. Jorgenson Reply

SIR: We are pleased to have stimulated such a lively debate on an important, but infrequently addressed issue. Our particular thanks go to John Nemiah, M.D., for his consistent willingness to open the pages of the *Journal*—in this, as in other instances—to the discussion of contemporary problems of major significance for psychiatry.

Given the diverse opinions expressed by us and our many correspondents, it may be useful to underscore one conclusion about which we all agree. Everyone concurs that sexual relationships between psychiatrists and their current patients are so likely to be exploitive and harmful that they should always be considered unethical. Indeed, given the difficulties the profession has had deterring such behavior, we favor making psychotherapists' sexual contact with patients a criminal offense.

There is less consensus, however, on parameters for post-termination relationships. The APA's rule since 1988 has been that sex with a former patient is "almost always unethical"

(1). (Prior to that APA had no formal position, and it was an open secret that many psychiatrists and other therapists had married former patients.) This position offers little guidance to therapists and provides little protection to patients, since the temptation exists to see every relationship as the exception envisioned by the rule. As Ms. Aronson says, "I have heard too often in presentations by some professionals in the community the advise that if you fall in love, simply terminate, refer the patient, and then see the individual." But hasty termination and immediate sexual contact with former patients may be as damaging to former patients as sexual contact during therapy. The current APA rule is clearly inadequate.

In our effort to devise an alternative approach more protective of both patients and therapists, we analyzed the factors that contribute to the exploitive nature of patient-therapist sexual relationships: patients' substantially impaired decision making, and the possibilities of coercion and fraud by therapists. We argued that as time passes after termination, with no further contact between patients and therapists, the salience of these factors diminishes, until a point is reached at which sexual relationships can no longer be considered exploitive. Recognizing the difficulty of line drawing, we proposed that sexual relationships with former patients that begin within 1 year after the last contact between therapist and patient be considered unethical per se. Should such relationships begin after 1 year with no contact whatsoever between patient and therapist, however, we argued that the risk of exploitation is sufficiently diminished and that there is insufficient justification for prohibition.

By proposing this rule it was *not* our intention to encourage sexual relationships with former patients. Indeed, compared with the indeterminate state of the current APA ethical guidelines on posttermination sexual relationships, we hope that our proposal will have the opposite effect. Since almost all intimate relationships now begin within 1 year after termination, our proposal should have the effect of diminishing the frequency of such relationships.

Our correspondents offer four main objections to our analysis, which we will consider in turn. Several writers urge that—by holding open the possibility of an intimate relationship in the future—our proposal would corrupt the course of therapy, which will deteriorate into verbal courtship or foreplay. Of course, the same could be said of the current APA position, which leaves open the possibility that any therapeutic relationship, with no interval whatsoever, could evolve into an intimate one. The current rule, whatever its deficiencies, has hardly led to the breakdown of boundaries in psychotherapy and the corruption of the therapist-patient relationship. Nor would our proposal.

In fact, compared with the status quo, a 1-year waiting period would be more protective of patients' interests. The "predatory" therapists whom Dr. Drummond fears we would encourage are not—we can state with assurance, having seen them in action in many cases—the kind of persons who will discontinue treatment, then wait 1 year without any further contact to initiate sexual relationships. As for the "love-sick" therapists about whom Dr. Gabbard has written (2), they will have a long interval in which to work through their countertransferences and obtain help for their own problems. Patients, too, freed of regular contact with an imposing authority figure, will have an opportunity to sort through their feelings and seek assistance in resolving them. Under our proposal, the consulting room would become a safer, not a more treacherous place.

A second objection is that—even if therapy is not impacted directly—we underestimate the persistence of former patients' transference to their therapists and the consequent enduring

impairment in their abilities to make decisions about relationships. It would be unfair, according to this argument, to allow former patients to enter into intimate relationships, even after a substantial period has passed. Perhaps that is true, but despite several letters' claims to the contrary, the empirical literature on transference lends little support to this assertion. The major studies, which deal solely with patients who have been in analysis, have serious methodological problems (3–5). Indeed, given the small number of subjects involved, they are more in the nature of case reports than systematic research. Further, the results of these and other studies (6, 7) are sufficiently ambiguous that they can be interpreted equally well as indicating the rapid diminution of transference over time as the contrary. Moreover, the research on transference has never addressed the most relevant issue for our purposes here: granting that patients will continue to have some sort of feelings about their former therapists, are those feelings generally of the nature and intensity to impair their decision making?

The absence of reliable research in this area is understandable. Transference, as several of the letters demonstrate, is an elusive concept, subject to definitional controversies and ill-suited to precise assessment. How should rule making deal with this problem? The current APA approach is to charge ethics committees with the responsibility for investigating the degree to which a relationship results from a former patient's "projection of feelings appropriate to another person at another point in time" (8). How many relationships could stand such a test? This is a recipe for idiosyncratic decision making of dubious validity.

We would take another approach. As Dr. Sonnenberg notes, correctly in our view, "Transferences are a ubiquitous part of everyone's life experience," including as Dr. Sapir points out, their love relationships. Rather than encouraging inquiry into whether a particular transference so impaired decision making as to warrant invalidating a person's choice—an approach that gives no prospective guidance—we would place the emphasis elsewhere. Common sense and clinical experience suggest to us that the intensity of transference diminishes over time without contact. A flat ban on intimate relationships during a period when transference effects are likely to be maximal seems a more reasonable and fairly administered approach. Several experienced practitioners who have written to us directly have suggested that a 2-year waiting period would be preferable to the 1 year we suggest. It may be. The precise interval is less important here than the idea of a fixed period.

A third contention offered by several writers is that our proposal ignores the likely consequences of posttermination relationships. Dr. Brown and colleagues cite limited data from a highly selected sample of persons who engaged in posttermination relationships, then sought subsequent therapy, to support the contention that most former patients will be harmed (9). In so doing, they ignore the authors' warning that "threats to the validity [of the data] are numerous." Even if these data are accepted as an accurate portrayal of the status quo, however, they have little relevance to our proposal. Most posttermination relationships now begin shortly after therapy ends, often having been arranged while treatment was in progress. That would not be possible under our approach. Thus, the data cited by Dr. Brown et al. tell us nothing about the likely consequences of our proposal.

In contrast, Dr. Schoener at the Minneapolis Walk-In Counseling Center (personal communication), whose clinic probably has the greatest experience with persons who engaged in intimate relationships with current and former therapists, reports a different impression. The vast majority of cases of which he is aware that began a year or more after termina-

tion started with unplanned social encounters between therapists and former patients. Moreover, almost all of these came to his attention through routes other than complaints by the former patients and involved no allegations of harm. To our mind, although both Dr. Schoener and Dr. Spindler affirm that harm may sometimes result, the question of its frequency is an open issue.

The final challenge to our proposal is in many ways the most important, and builds on the previous objections. If lingering effects of transference *may* affect former patients' decision making, even years after termination, and if harm *may* sometimes result from posttermination sexual contact, why should we risk these effects, whatever their frequency? Would a permanent ban on posttermination sexual relationships not be the best solution of all?

Regulation of posttermination relationships involves a balancing of several important considerations: a desire to protect former patients from the adverse consequences of their decisions to engage in intimate relationships with their therapists and their rights (and therapists' rights) to privacy and freedom of association. This conflict between paternalism and autonomy (to use the ethical, rather than the legal terms) arises whenever rule making aims at controlling private behavior. Our constitutional system has worked out a compromise: when the state seeks to infringe on citizens' fundamental rights, it must prove a compelling interest to do so, and even then it must choose means that are least restrictive of those rights (10).

With regard to sexual relationships between patients and current therapists, we believe the likelihood of harm and the unfairness to patients establishes a compelling interest in regulation. Moreover, we are persuaded that no less restrictive means than a total proscription will be effective. As described above, however, the case is much less clear when it comes to posttermination relationships. The vast preponderance of harm comes from relationships begun soon after termination. With a substantial waiting period, neither harm nor impairment of patients' capacities to make their own decisions has been demonstrated. In such a context, no compelling state interest supports a permanent ban on posttermination relationships. The state's interests in protecting former patients—a real one—can be achieved less restrictively by the sort of time-limited ban we have suggested.

Drs. Anderson and Drummond, however, ask why a "legal" analysis should dominate here. Can APA not elect to adopt stricter standards than would be sanctioned by the law? The answer is that, as a private organization, APA is not bound by constitutional considerations in the same way as is a state. But there are two reasons why it would be a mistake too readily to reject the constitutional argument outlined above. First, in our view, there is little difference in this case between the issues that enter into a constitutional analysis and those that ought to be considered from an ethical perspective. Autonomous choices about intimate relationships ought to be respected in general, barring strong countervailing reasons for not doing so. Ethics and law differ little in this regard.

More important still is the question of what impact we want our ethical rules to have. If they are to serve as guidelines for licensing boards and courts, who in contrast to APA can impose meaningful sanctions, they must abide by constitutional desiderata. There may be some autarkic satisfaction in creating a rule of presumed ethical purity, but there is much more impact in creating a standard that can be widely adopted in our society, and stands some chance of serving as a useful deterrent.

We note, in this regard, Dr. Pincus's question as to how our analysis would apply to other, nonpsychotherapeutic, and even nonphysician groups. He notes, and we concur, that re-

relationships other than the therapist-patient one, including doctor-patient, lawyer-client, teacher-pupil, and supervisor-supervisee, are plagued with questions about the appropriateness of subsequent sexual contact. A virtue of the approach we suggest is that it serves as a model for other relationships in which similar problems of impaired decision making, coercion, and fraud may arise. The right answer may be to prescribe intimate relationships until some time has passed after the professional relationship has ended.

Given the limitations of space, we apologize for not being able to address every question raised by all of our correspondents, but we look forward to continuing discussions in the pages of the *Journal* and elsewhere.

Tranylcypromine Abuse: Cause for Concern?

SIR: The recent case report by Kathleen Theresa Brady, M.D., Ph.D., and colleagues (1) highlights the possible abuse potential of tranylcypromine. It is the only monoamine oxidase inhibitor (MAOI) that has been linked to abuse potential, which seems to be related to its amphetamine-like properties. This includes a chemical structural similarity to amphetamine as well as some metabolism to amphetamine (2). Chronic use of tranylcypromine can lead to habituation and a withdrawal state. These withdrawal effects are unpleasant and not too prolonged except in those rare cases where the drug has been abused (3). It is clear that although such cases do indeed occur, they are extremely rare. This is brought out by the fact that in a 1969 book on MAOIs (4), among other psychoactive drugs, there was no evidence that chronic treatment with MAOI induced physical dependence or withdrawal symptoms after termination of treatment. It is clear that the rarity of tranylcypromine abuse is due to the fact that its abuse is directly related to its amphetamine-like properties and to its

partial metabolism to amphetamine; which seems only to occur at very high dosage levels of the agent. Such high doses invariably cause marked CNS stimulation and delirium, as was found in the case reported by Dr. Brady and colleagues, where doses of approximately 300 mg/day were ingested (1). This dose seems to be close to the fatal dose of tranylcypromine, since a successful suicide with this agent at an acute dose of 500 mg has been recorded (4).

In order to prevent even the rare occurrences of tranylcypromine abuse, it seems essential to forewarn the patient of its abuse potential and the potentially fatal outcome of such abuse. Monitoring of patients who respond rapidly and dramatically to therapeutic doses of tranylcypromine would seem essential, since it is this type of patient that appears to run the greatest risk of abuse.

It must be emphasized that this valuable antidepressant should not be eschewed for fear of its abuse potential, which is extremely low and which can be obviated by appropriate counseling and monitoring.

Dr. Brady and Associates Reply

SIR: We would like to thank Drs. Lichtigfeld and Gillman for the interesting and thoughtful comments which they offer. They suggest that the lack of physical dependence and withdrawal after chronic treatment with MAOIs helps to explain the rarity of abuse of these substances. It is important to note that production of physical dependence can be independent of the abuse potential of a drug. Some very common drugs of abuse, including marijuana and cocaine, do not produce clear-cut physical dependence. While it is indeed true that the MAOIs do not produce physical dependence, this does not necessarily have much bearing on the abuse potential of this group of agents.

We agree with the assertion that tranylcypromine abuse is rare, but we feel that it is important to note that the cases reported in the literature all involve individuals with a history of substance abuse. This fact coupled with the increasing prevalence of substance abuse could lead to increased MAOI abuse in the future. More importantly this may help to identify a patient group at risk for abusing these substances, so that they could be targeted for more careful counseling and monitoring when MAOI treatment is initiated. We agree completely with the authors' assertion that these are valuable therapeutic agents which can be safely used when properly monitored.

Dynamic Cognitive Therapy Anyone?

SIR: Kenneth Z. Altshuler, M.D., in his review of *Cognitive Therapy of Personality Disorders* by Aaron T. Beck and Arthur Freeman (1), noted with a wink the concordance of cognitive and psychodynamic therapies for personality disorders. Dr. Altshuler noted similarities regarding transference, explorations of the past, countertransference, and the need for frequent therapy sessions for extended periods. He said this made him "rather wonder."

I wonder, too, why no one has melded cognitive and dynamic theory in the grand fashion of our best but disparate cognitive and dynamic theorists. Call it "dynamic cognitive therapy." I can think of no better therapist than one capable of dynamic understanding and interpretation, who can use cognitive techniques to help patients put into action the fruits of their psychodynamic insights. This hybrid therapy no doubt occurs in offices around the globe, by accident or design. What is missing is academic sanction by formal attention and fleshing out of the details.

There are suggestions today that in order to prove psychotherapeutic efficacy (and perhaps to justify reimbursement?), we must follow a given "instruction manual" for a given psychotherapy. We might do ourselves a favor to acknowledge more formally that good therapy can borrow from separate camps. Our separate camps may not be so separate.

Back to dynamic cognitive therapy. Is anyone out there developing this? I would be interested in hearing from you.

Psychodynamic Psychiatry in the "Decade of the Brain"

Glen O. Gabbard, M.D.

***Objective and Method:** To illustrate the continued relevance of psychodynamic thinking in the practice of contemporary psychiatry, the author reviews a number of studies that demonstrate the intimate connection between psychosocial and neurophysiological factors in the etiology and pathogenesis of psychiatric disorders. A survey of three specific anxiety disorders illustrates the complex interaction between mind and brain in these disorders. **Results:** Research on both primates and humans suggests that psychological influences result in permanent alterations of a neurobiological nature. Similarly, psychological interventions in a treatment context may have a profound impact on neurophysiology. Clinical case examples demonstrate that "biologically based" disorders may be rich in unconscious meaning. Clinical understanding of the meaning of symptoms may be instrumental in ensuring patients' compliance with pharmacotherapy regimens and in the removal of other resistances to treatment. **Conclusions:** In contemporary psychiatry, a psychodynamic perspective must be preserved. Without it, meaning will be lost, and both diagnostic understanding and informed treatment planning will suffer as a result.*

(Am J Psychiatry 1992; 149:991-998)

Now that the "decade of the brain" is well launched and remarkable discoveries from the neurosciences fill the pages of our journals, the time may be ripe for a reexamination of the continued relevance of psychodynamic thinking to both clinician and researcher. Two trends in contemporary psychiatry have been increasingly disconcerting to those of us who view clinical work as an optimal integration of mind and brain: 1) the "either-or" polarization of the psychodynamic and the biological and 2) the devaluation of psychodynamic understanding and therapy as increasingly irrelevant. Psychodynamic psychiatry is not inherently "antibiological," and it has much to contribute to modern clinical practice.

In asserting the continued applicability of dynamic approaches, I wish to clarify that I am conceptualizing

psychodynamic psychiatry as much broader than dynamic psychotherapy, which is but one component of the dynamic psychiatrist's armamentarium. As I have noted elsewhere (1), "Psychodynamic psychiatry is an approach to diagnosis and treatment characterized by a *way of thinking* about both patient and clinician that includes unconscious conflict, deficits and distortions of intrapsychic structures, and internal object relations" (p. 4). This mode of thought includes such factors as unconscious meaning and the reexperiencing of past relationships in the present with the clinician. Within the broad scope of this definition, treatment measures other than psychotherapy, such as dynamic pharmacotherapy and dynamically informed hospital treatment, are aspects of dynamic psychiatry.

PSYCHOLOGICAL VERSUS BIOLOGICAL ETIOLOGY

Much of the polarization between the biological and psychodynamic perspectives arises from a failure to appreciate the complex relationships between psychoso-

cial and neurophysiological factors in the etiology and pathogenesis of psychiatric disorders. It is commonplace in clinical practice today to hear patients report that they have been told they have a "chemical imbalance." This oversimplified and reductionistic explanation is problematic from a number of standpoints (2-4). Lipowski (2) expressed his concern as follows:

It confuses the distinction between etiology and correlation, and cause and mechanism, a common confusion in our field. It gives the patient a misleading impression that his or her imbalance is *the* cause of his or her illness, that it needs to be fixed by chemical means, that psychotherapy is useless, and that personal efforts and responsibility have no part to play in getting better . . . To assume, as we all do, that biochemical processes underlie mental activity and behavior does not imply that they are the causal agents but rather constitute mediating mechanisms. They are influenced by the information inputs we receive from our body and environment and by the subjective meaning of that information for us. It is that meaning which largely determines what we think, feel and do. (p. 252)

Neurochemical and neuroanatomical changes in the brain may be causally related to psychosocial influences in the environment and to the meaning attributed to those influences. As a corollary to this point of view, psychotherapeutic interventions may result in permanent alterations in brain functioning. In a much touted series of experiments with the marine snail *Aplysia*, Kandel (5-7) convincingly demonstrated that the functional effectiveness of synaptic connections can be altered by learning experiences connected with the environment, specifically, through regulation of gene expression. Kandel (5) concluded, "It is only insofar as our words produce changes in each other's brains that psychotherapeutic intervention produces changes in patients' minds. From this perspective the biological and psychological approaches are joined" (p. 1037). Although psychotherapy uses the language of meanings, there can be little doubt that inasmuch as events of learning and memory have an impact on the brain, it can be viewed as a biological process (6).

The phenomenon of kindling may illuminate some of the processes involved in the triggering of neural mechanisms by psychological/environmental etiological factors. Gold et al. (8, 9), drawing on the work of Post et al. (10), postulated that painful events, such as separations or losses, early in life may sensitize receptor sites, leading to vulnerability to recurrent depression in adulthood. They pointed out that ideas and images associated with depressive states could ultimately act as conditioned stimuli capable of eliciting a major depressive episode even without a concrete loss or external stressor in the environment. This model is in keeping with the observation that chronic stress and loss early in life may leave people vulnerable to depression as adults. The model is also consistent with psychoanalytic observations that an imagined loss or a perceived discrepancy between idealized expectations and reality may precipitate depression. Gold et al. concluded from this model that major depression is best treated with a

combination of medication and psychotherapy, because the inner conflict brought on by prior life events may increase the burden of stress unless it is addressed psychotherapeutically. They also pointed out that simple equations of depression with single neurotransmitters are no longer tenable, as our knowledge of the complexity of the neurotransmitter systems has increased with more and more sophisticated neuroscience research.

Primate research has been of extraordinary heuristic value in demonstrating the impact of psychological trauma on brain functioning. Squirrel monkeys separated from their mothers experience elevated plasma cortisol levels. If the separations are repeated, these physiological changes become permanent (11, 12). Primate research also suggests that the opioid system is intimately involved in the regulation of separation anxiety and that social isolation has a direct impact on the sensitivity and number of brain opiate receptors (13). Other long-lasting neurobiological changes resulting from early maternal separations include changes in adrenal gland catecholamine-synthesizing enzymes (11, 12), changes in hypothalamic serotonin secretion (14-16), and lasting alterations in the sensitivity of noradrenergic receptors (17). Imipramine and other agents that increase noradrenergic activity at the synapses alleviate the effects of separation and social isolation in monkeys (18).

The psychodynamic notion that psychological trauma may be more or less damaging, depending on the critical developmental phase during which it is inflicted, is also supported in principle by primate studies. In Suomi's research on the impact of maternal deprivation (19), the effects of removing infant monkeys from their mothers were much more striking if the separation occurred at 90 days than if it occurred at either 60 or 120 days, possibly because of a link between myelination of the nervous system and certain kinds of bonding behavior (13).

After an extensive review of the primate research, van der Kolk (13) concluded:

There may be actual morphological changes in the brain following social deprivation, or other disruptions of affiliative bonds. There also is evidence that the number and nature of brain receptors for particular neurotransmitters can continue to change throughout a person's lifetime, as illustrated by dopamine receptor alterations leading to the clinical symptoms of tardive dyskinesia . . . Thus it is conceivable that receptor changes induced by early deprivation or trauma in the CNS can to some degree be modified by later life experiences. (pp. 50-51)

These primate studies not only support the kindling model based on psychological trauma, such as separations, but they also lend credence to the idea that the brain is possessed of remarkable structural plasticity. We now know that morphological changes in brain cells occur nearly every day and that massive trauma is not necessary to induce such changes (20-22). The influence of psychosocial factors on neurobiological

processes can be seen in changes that occur as a result of psychotherapy as well as in pathological states, such as posttraumatic stress disorder (PTSD), in which recurring intensive stimulation from the environment exceeds the capacity of the cortex to process what is happening and leads to synaptic changes of a permanent nature. The fact that one person will respond with PTSD to a situation that leaves no permanent mark on another reflects the fact that the subjective meaning given to the environmental stimulus is critical in effecting synaptic changes.

Conversely, one can also observe the impact of biology on psychology in the aging process. As Roose and Pardes (21) have suggested, the well-known "mellowing" phenomenon of middle age, associated with a shift to more mature defenses (23), may well be linked to the dramatic drop-off in the amount of norepinephrine in the locus ceruleus between the ages of 40 and 60.

The foregoing survey of the mutual influence of psychology and biology in the human psyche attests to the inseparability of brain and mind. A number of leading figures in our field (2, 3, 24-28) have warned of the dangers inherent in the "remedicalization" of psychiatry—namely, that psychiatry might become "mindless." Mindless psychiatry loses the domain of meaning. The essential role that meaning plays, even in disorders with significant biological underpinnings, can be illustrated by a detailed examination of three common anxiety disorders.

OBSESSIVE-COMPULSIVE DISORDER

There is abundant evidence that obsessive-compulsive disorder is an illness with a strong biological component. Monozygotic twins have a higher rate of concordance for the disorder than their dizygotic counterparts, there is an increased prevalence of the disorder in patients with Tourette's syndrome and in their families, and there is a dramatic response in some patients to psychosurgery and clomipramine (29-31). A quantitative study in which computerized tomography was used also demonstrated a smaller caudate nucleus volume in patients with obsessive-compulsive disorder than in healthy control subjects (32). Finally, patients with obsessive-compulsive disorder show virtually no response to placebo, in contrast to patients with other anxiety disorders (33).

To provide a convincing case for the ongoing relevance of psychodynamic thinking in contemporary psychiatry, there must be a demonstrable advantage to a psychodynamic approach. However, there is little evidence in the literature to suggest that dynamic psychotherapy or psychoanalysis is effective in the treatment of obsessive-compulsive disorder (34). As the following case illustrates, however, dynamic principles are of great value even in the treatment of "biologically based" disorders, and the somatic therapies used to treat them are often imbued with psychodynamic meanings.

Case vignette. Mr. A was a 29-year-old unmarried man with obsessive-compulsive disorder. At the time he presented for psychiatric hospitalization, he reported a 10-year history of obsessive-compulsive symptoms, and he complained of being totally housebound for the last 8 years because of constant, incapacitating, "grotesque, horrific" thoughts that never ceased. Eight years before admission, when Mr. A became housebound, his mother retired from her job so she could take care of him at home and meet his demands for cleanliness. Her life revolved around him.

Mr. A was obsessed with the need to avoid contamination. He also worried about making women pregnant, because he feared he might have semen on his hands. Hence, he became a compulsive hand washer. He insisted that his mother had to be with him 24 hours a day. Although she did not sleep with him or go into the shower with him, she did help him dress so that he would not touch his clothes and become contaminated. He also required her to follow an elaborate 58-step ritual while cooking his food and placing it on the table. If she did not follow this ritual precisely, she had to discard the entire meal and start over again. She threw out thousands of dollars worth of food each year in order to respond to these demands. Mr. A also insisted that his father either stay away from home or remain in another part of the house so he would not be contaminated by germs that his father brought home from work.

Mr. A's early childhood development was reportedly unremarkable, but he did recall a very unpleasant event when he was approximately 5 years old. He remembered seeing his father grab his mother by the breasts while she cried for the patient to rescue her. He tried to stop his father, but he was overpowered by the older man. He remembered feeling terrible about the incident, and he cried because he was unable to rescue his mother.

Although Mr. A had been to numerous psychiatrists, he always refused to go back after one visit. At one time he agreed to take clomipramine, but he stopped after the first dose because he said the side effects bothered him. His parents finally felt that they had to hospitalize him because he was incapacitated. When he came to the hospital, I asked him why he was seeking treatment. He responded, "I'm determined to be dependent—I mean, independent." I commented to him that he had first said "dependent," and I inquired, "Is there perhaps a part of you that would like to be dependent?" Mr. A responded, "You mean on my mother?" I replied that I thought he would know better than I. Mr. A reflected a moment and said, "Well, she does take pretty good care of me."

Mr. A's slip of the tongue provided a glimpse into the unconscious motivations for his resistance to treatment. Any kind of successful treatment threatened his dependent relationship with his mother. If clomipramine were likely to help him, then he would not take it. Similarly, he would defeat all other outpatient or inpatient treatment efforts as well.

After about a week of hospitalization, Mr. A defied my expectations. He began to make dramatic improvements. He could touch doorknobs without fearing contamination, he could read magazines that others had touched, and he greatly decreased the time he spent washing his hands. This improvement occurred without medication. Mr. A commented that he felt "a lot less nervous" in the hospital than he had expected. As I explored with him how the hospital setting might have reduced his anxiety, it became apparent that he had been increasingly worried about his sexual wishes toward his mother. He commented that when his mother dressed him, he felt that "there was something sexual about that." Removing him from the emotionally charged household made his sexual

wishes toward his mother much less problematic for him. Similarly, aggressive wishes to keep his father out of his life were less troubling. Because his anxiety about both sexual and aggressive wishes had diminished, his obsessive-compulsive symptoms were not needed so extensively to bind his anxiety.

The case of Mr. A beautifully illustrates the interface between the psychodynamic and the biological. However biologically driven his obsessive-compulsive symptoms may have been, they also revealed a symbolic wish to win his mother's affection away from his father, as poignantly depicted in his early childhood memories. His symptoms reflected the core psychodynamic concept known as compromise formation; that is, they contained both the direct expression of an underlying wish and a defense against that wish (35). Mr. A's compulsive rituals served as a defense against his sexual longings for his mother by consuming all his time in hand washing and various other exercises. However, these symptomatic rituals also resulted in his being dressed by his mother and receiving all her attention, while his father stayed away from home. Hence, the symptoms had the dynamic meaning of fulfilling his childhood wish to steal his mother away from his father. Taking clomipramine or receiving any other form of treatment threatened this triumph by putting him in a position in which he no longer needed his mother. On the other hand, this oedipal victory created enormous anxiety and guilt, which increased his recourse to rituals and obsessions. When removed from the triangle he had established with his parents at home, Mr. A had much less need of his obsessive-compulsive symptoms to deal with the anxiety and showed remarkable improvement.

Consider an analogy: when a magnet is placed under a sheet of paper containing iron filings, the filings line up in formation on the surface and follow the movement of the magnet along the underside of the paper. In a similar manner, psychodynamic issues frequently appropriate magnet-like biological forces for their own purposes. In this manner Mr. A's unconscious wishes and his defenses against them attached themselves to the biologically driven obsessive-compulsive symptoms and used them as a vehicle for their expression.

Although formal dynamic psychotherapy was not used in the treatment of Mr. A, the dynamic understanding of his resistance to pharmacotherapy and to treatment in general was essential in explicating his refusal to take clomipramine and to cooperate otherwise with treatment. In fact, Mr. A's slip of the tongue led to his awareness that any improvement in his symptoms might cause him to lose his privileged position with his mother.

The case of Mr. A also underscores the importance of a psychodynamic approach to pharmacotherapy for cases in which compliance is a problem. Failure to comply with pharmacotherapeutic regimens often can be understood along conventional lines of transference, countertransference, and resistance issues (1). A considerable literature on the practice of dynamic pharmacotherapy has accrued (36-45), and there has been a

broad consensus that psychodynamic meanings of medications may pose formidable obstacles to compliance with medication regimens.

PANIC DISORDER

Nearly 100 years ago Freud (46) identified two forms of anxiety. One form, which he termed "actual neurosis," allegedly resulted from physiological buildup of libido and was manifested by an overwhelming sense of panic accompanied by symptoms of autonomic discharge. In contrast to this form of anxiety, which he did not view as resulting from psychological factors, he observed another variant that originated in a repressed thought or wish and was manifested as a diffuse sense of dread or worry. By 1926, as a result of his tripartite structural model of id, ego, and superego, Freud had further refined his understanding of anxiety. He now viewed it as the result of intrapsychic conflict between aggressive or sexual wishes emanating from the id and complementary responses from the superego in the form of threats of punishment. Anxiety was conceptualized as a *signal* reflecting a danger in the unconscious. In response to this signal, the ego would mobilize defense mechanisms to prevent unacceptable feelings and thoughts from emerging into consciousness. Surprisingly ahead of his time, Freud had already differentiated what we now know as panic disorder from anticipatory anxiety (47, 48).

Elaborating on Freud's early formulations, Nemiah (48) postulated that patients who display symptoms of panic disorder must have an underlying neural structure that can be triggered by psychological and physiological factors. In patients without that neural structure, a milder form of anticipatory or signal anxiety will result.

The neural structure referred to by Nemiah (48) has been further linked to the locus ceruleus by modern neurobiological researchers (49). Dysregulation of γ -aminobutyric acid (GABA) in the locus ceruleus appears to serve as a biologically based etiology of panic disorder (50). Imipramine, which is a highly effective agent in blocking panic attacks, also decreases the firing rate of the locus ceruleus (51). Further evidence of a biological basis for panic disorder includes the induction of panic attacks by sodium lactate infusion in most patients with panic disorder (52), a higher incidence of panic disorder in panic patients' families than in control subjects' families (53), and a 31% concordance for panic attacks in monozygotic twins compared to 0% for dizygotic twins (54).

Although the evidence for neurophysiological factors in panic disorder is impressive, these observations are more persuasive with respect to pathogenesis than to etiology. None of the neurobiological data explain what triggers the onset of a panic attack. In a pilot study in which analysts conducted psychodynamic interviews with nine consecutive patients with panic disorder, an objective research psychiatrist was able to identify mean-

ingful stressors preceding the onset of the panic attacks in every case (51).

Indeed, there are several lines of evidence suggesting that psychological factors may be relevant to panic attacks (1). In the months preceding the onset of panic disorder, patients with the disorder had a higher incidence of stressful life events, particularly loss, than did control subjects (55). Also, in one study (56), 50% of 32 patients with agoraphobia had histories of separation anxiety, and in this group panic attacks often followed the loss of a significant person. In another controlled study of patients with panic disorder (57), the experimental group not only had significantly more life events in the year preceding the onset of panic, but they also experienced greater distress about events in their lives than did the control subjects. The research suggests that panic episodes which appear to be without psychological content and which seem to emerge "out of the blue" may in fact be triggered by *unconscious* psychological factors.

From this perspective, one can argue that the etiology of panic may well involve the unconscious meaning of events, while the pathogenesis may involve neurophysiological factors triggered by the psychological reaction to the events. Busch et al. (51) concluded, "Since each individual interprets the meaning of these events differently, an external stressor may or may not lead to the onset of panic in a neurophysiologically susceptible individual. This suggests that there is a crucial psychological variable that mediates between external events and panic onset" (p. 321).

Some of the most intriguing data regarding panic disorder concern the rate of response to placebo. Anywhere from 25% (58, 59) to 43% (60) of patients with panic disorder show improvement with placebo. These findings are striking when compared to the almost total absence of response to placebo in patients with obsessive-compulsive disorder. Such a dramatic response to placebo is certainly suggestive of psychological factors at work. It may well be that transference factors involved with receiving a pill from a concerned physician work to alleviate the symptoms.

In patients with borderline personality disorder who have not developed the capacity to summon a soothing, holding introject to calm them in times of stress (61), a full-blown panic attack may develop over long weekends when they have no contact with their psychotherapist. Because they cannot evoke an internal image of the therapist, they may begin to fear that the therapist has died or has abandoned them. Under such circumstances, the borderline patient may call the therapist to be reassured by the sound of his or her voice. Hearing just a few words from the therapist over the telephone may immediately terminate the panic attack, as quickly as any pharmacotherapeutic agent.

In this situation, we once again see how neural mechanisms (in the locus ceruleus, in this case) can be influenced as profoundly by psychotherapeutic intervention as by chemical agents. In Waldinger and Gunderson's study of successfully completed long-term psychody-

namic psychotherapy of borderline patients (62), they found that by the fifth year, none of the patients experienced panic in response to their therapist's departures, further evidence suggesting that psychotherapy may produce permanent neurophysiological alterations.

Cognitive-behavioral treatments have also proved effective in the treatment of panic disorder. A recent study by Shear et al. (63) has even demonstrated that lactate induction of panic can be effectively reversed through successful cognitive treatment. These findings, coupled with a variety of case reports of successful treatment of panic disorder with either psychoanalysis or psychodynamic psychotherapy (1, 64-66), provide persuasive evidence that psychological interventions have a major role to play in the treatment of panic disorder.

GENERALIZED ANXIETY DISORDER

The flurry of excitement associated with the significant breakthroughs in panic disorder research have to some extent obscured the continued psychodynamic importance of signal anxiety, as originally described by Freud. This less dramatic variant of anxiety is probably not generated in the locus ceruleus in the same manner as panic disorder (21). Signal anxiety, however neurophysiologically generated, is an enormously informative gateway into the unconscious conflicts residing in the human psyche.

One of the unfortunate consequences of the revised nomenclature in *DSM-III* and *DSM-III-R* is that anxiety is now treated as a disorder in its own right, instead of recognizing that in certain cases it is a signal of unconscious turmoil that deserves investigation. In writing about anxiety from a psychoanalytic viewpoint, Appelbaum (67) referred to it as "a universal, and in that respect normal, phenomenon which may be at any given moment, for any given person, adaptive or maladaptive, too intense or too mild, centered around substitute objects rather than the originally feared ones, an aspect of existential uncertainty or 'neurotic' conviction" (p. 164). The quantitative view of anxiety implies that "less is better." In the assessment of subjects in the Menninger Foundation Psychotherapy Research Project, 18 of 35 patients showed increased anxiety at termination of psychoanalysis or psychotherapy (67). However, 13 of these 18 patients were judged by independent raters to have changed for the better. In evaluating these results (67, 68), the investigators differentiated between primary anxiety, which is disorganizing to the patient (analogous to panic disorder), and anxiety used as a signal. The researchers noted that an increase in tolerance of anxiety, defined as a capacity to experience anxiety without having to discharge it, often occurs as a result of dynamic psychotherapy and reflects expansion of the ego. Many of the improved patients showed a striking capacity to use ideational activity more efficiently in the service of binding anxiety. The investigators concluded that the mere pres-

ence or absence of anxiety after treatment was not sufficient to understand or evaluate change. It may well be that greater ego mastery over anxiety allows one to confront certain existential concerns inherent in life in a more forthright manner.

Anxiety will appear in numerous situations over the course of the life cycle. Whether patients should resort to medication each time they are anxious should be a question of considerable concern to psychiatrists. One can eliminate physiological components of anxiety with medication without addressing the remaining cognitive aspects of the worry. The following vignette is illustrative.

Clinical vignette. Ms. B was a 23-year-old graduate student who came for consultation because of periodic episodes of intense anxiety. About three times a month she would begin worrying about death while lying in bed. Typically, she would start ruminating in the following manner: "I am 23 now; in only 7 years, I'll be 30. Then I'll be 40, and my kids will be grown. Then I'll be a grandparent and retire; and then I'll die." These thoughts led to concerns that her parents, both of whom were alive and well, would soon die. As these thoughts escalated, the anxiety she experienced increased to the point where her heart was racing and she could not fall asleep.

After diagnostic evaluation, I discussed several possible interventions with her: prescription of antianxiety medication, psychotherapeutic exploration of the causes of her anxiety, or a combination of the two. She told me pointedly that she had no interest in medication. "How can a pill make my fear of death go away?" she inquired. She made it clear that she wanted to understand the origins of her anxiety so she could master her fears.

I embarked on a course of psychotherapy with Ms. B that led to increasing ideational mastery over the disturbing affect. I empathized with Ms. B regarding the frightening nature of death, but I noted that concerns about living often contributed to fears about death. I asked her what was going on in her life that might contribute to her anxiety. She immediately replied that it had nothing to do with her husband's being stationed overseas. Tears came to her eyes, and I handed her a box of tissues.

Ms. B ignored the box of tissues and continued talking about how young people were dying of AIDS and cancer. I asked her why she had not taken a tissue when I had offered it to her. She told me she thought it would have been a sign of weakness. I wondered with her if it had always been difficult for her to acknowledge that she needed the help of other people. She responded that all her life everyone had told her their problems, and she could never acknowledge that she had problems and needed help from others. I suggested to her that she might need to present a pseudoindependent facade as a way of denying her neediness. She readily acknowledged that she dreaded the feeling of weakness associated with being vulnerable and needy. I pointed out to her that death was the ultimate situation of vulnerability and neediness. She then responded that the worst thing about death, in her mind, would be having to go through it alone.

As we continued to explore sources of her anxiety, Ms. B revealed a history of having significant difficulties with the expression of anger. She feared that her anger would come out in an explosion that would drive others away from her. Her nighttime anxiety often arose after seeing violent movies. She said it bothered her a great deal that others expressed their

anger in such a violent, forthright manner while she worked so diligently to control hers. Further psychotherapeutic exploration led to the uncovering of a good deal of anger at her father that she had been unable to express. Her unconscious concern was that her anger would be so explosive that it would destroy him.

After 2 months of psychotherapy, the episodes of intense anxiety disappeared. Ms. B still worried about death to some extent, but she had developed greater mastery over the fear as she understood the underlying concerns about the impact of her anger and her fears of being abandoned and alone. In other words, a broadened ideational mastery of the affect enabled her to control her symptoms.

The case of Ms. B illustrates the time-honored principle that in clinical psychiatry we must adapt the treatment to the patient. Contrary to the point of view of some third-party payers, the most appropriate treatment for a patient is not necessarily the most cost-effective. While some clinicians would argue that an antianxiety agent might have more quickly and more cheaply eliminated the patient's symptoms, Ms. B was asking for something other than symptom relief. As Barber and Luborsky (69) have argued, specific anxiety disorder diagnoses require different treatments in different circumstances with different patients. Psychodynamic psychotherapy may be the treatment of choice for the patient who is psychologically minded, motivated to understand the matrix from which the symptom arises, and willing to invest the time, money, and effort in a therapy process. Ms. B did not ask for medication and would probably not have taken it if it had been prescribed.

Disturbing affective states, such as anxiety, are protean in cause and meaning. In some cases anxiety may reflect an apparently random electrochemical burst from the locus ceruleus. In other cases anxiety may serve as a window on unconscious conflict. Following Freud's suggestion of a developmental hierarchy of anxiety, the psychodynamic psychiatrist can explore the specific cognitive correlates of the affect to gain a greater understanding of the origins of the patient's fears. These origins range from the most primitive anxieties—those having to do with disintegration or merger—to more mature concerns about loss of love or castration (1).

CONCLUSIONS

In this communication I have sought to demonstrate the continued relevance of psychodynamic thinking in contemporary psychiatry. A considerable body of research has demonstrated that the human brain undergoes significant functional and anatomical change in response to psychological influences. While this survey has focused on anxiety disorders, similar illustrations of the mutual interplay between the biological and the psychological could be drawn from a myriad of other psychiatric disorders.

To lose the psychodynamic perspective is to lose the

complexity and richness of human functioning in the quicksand of neurotransmitters and molecular genetics. Meaning must be preserved. It is instrumental to the induction of neurobiological changes associated with psychopathology. That which is crucial to etiology and pathogenesis will also be crucial to informed treatment planning. To our great good fortune, mind and brain are inseparable; hence, the "decade of the brain" holds the promise of clarifying their interrelationship.

Transduction of Psychosocial Stress Into the Neurobiology of Recurrent Affective Disorder

Robert M. Post, M.D.

Early clinical observations and recent systematic studies overwhelmingly document a greater role for psychosocial stressors in association with the first episode of major affective disorder than with subsequent episodes. The author postulates that both sensitization to stressors and episode sensitization occur and become encoded at the level of gene expression. In particular, stressors and the biochemical concomitants of the episodes themselves can induce the proto-oncogene c-fos and related transcription factors, which then affect the expression of transmitters, receptors, and neuropeptides that alter responsivity in a long-lasting fashion. Thus, both stressors and episodes may leave residual traces and vulnerabilities to further occurrences of affective illness. These data and concepts suggest that the biochemical and anatomical substrates underlying the affective disorders evolve over time as a function of recurrences, as does pharmacological responsivity. This formulation highlights the critical importance of early intervention in the illness in order to prevent malignant transformation to rapid cycling, spontaneous episodes, and refractoriness to drug treatment.

(Am J Psychiatry 1992; 149:999-1010)

The attacks [of manic-depressive illness] begin not infrequently after the illness or death of near relatives . . . We must regard all alleged [psychic] injuries as possibly sparks for the discharge of individual attacks, but . . . the real cause of the malady must be sought in permanent internal changes, . . . which are innate . . . In spite of the removal of the discharging cause, the attack follows its independent development. But, finally, the appearance of wholly similar attacks on wholly dissimilar occasions or quite without external occasion shows that even there where there has been external influence, it must not be regarded as a necessary presupposition for the appearance of the attack.

—Kraepelin (1)

Unipolar and bipolar affective disorders tend to be not only recurrent but also progressive in the sense that successive episodes occur after shorter intervals of remission, or with increased rapidity of cycling. Approximately 70% of the patients who have a first episode of unipolar affective illness have subsequent episodes, and almost all of the bipolar disorders are re-

current. In a series of studies with large numbers of subjects, which have been reviewed elsewhere (2-4), the median course of illness tended to be characterized by long intervals between early episodes of affective disorders but, with successive recurrences, a progressive shortening of these intervals of remission. While subgroups of patients may show a stable frequency of cycling over time, rapid cycling from the outset, or the more rare variant of "burnout," the tendency for progression appears to be modal across the majority of studies in which the intervals between successive episodes were systematically observed and recorded. These observations have helped to refocus neurobiological theorizing beyond the acute episode to the longitudinal course of affective illness and its tendency for recurrence and progression.

Previously, my colleagues and I (2, 3) have suggested that two preclinical models, behavioral sensitization to psychomotor stimulants and electrophysiological kindling, might provide useful and indirect bridging analogies to help conceptualize various aspects of the neurobiology of the course of affective disorders. This article will focus on accumulating clinical data that suggest the applicability of these models to triggering of episodes by psychosocial stressors and on new neurobiological data that may help conceptualize how this might occur. Thus, the advances reviewed arise in two research realms. Increasing evidence in one area suggests that the first episode of affective disorder, whether it is manic or depressive, is more likely to be associated with major psychosocial stressors than are episodes oc-

curing later in the course of the illness. The second line of new data arises from recent discoveries in neurobiology indicating how electrical and chemical stimulation and psychosocial stressors affect gene expression and thus present a way in which acute events can have long-lasting effects on the subsequent reactivity of the organism. These data on psychosocial stresses and their potential long-term impact are paralleled by a greatly enhanced understanding of the macro- and molecular biology of sensitization and kindling, thus allowing for more precise conceptualizations of processes that might be pertinent to the longitudinal course of affective disorders.

DIFFERENTIAL IMPACT OF PSYCHOSOCIAL STRESSORS IN FIRST AND SUBSEQUENT EPISODES

A greater role of psychosocial stressors in the initial episode of affective disorder than in subsequent epi-

sodes was observed by early investigators (1, 5–7 [7 also cited in 8]). More recently, systematic studies have explicitly tested and confirmed the notion highlighted in the opening quotation by Kraepelin that there is a greater role for psychosocial stressors in the initial episode than in subsequent episodes. These studies (8–19) are summarized in table 1 and, along with others (20; J. Mendlewicz, personal communication, 1990; M. Thase, personal communication, January 1991; G. Brown, personal communication, September 1991), are noteworthy in that they used a wide variety of measures of the impact of social stressors, ranging from global assessments to detailed systematic measures, such as the Paykel Life Events Scale (13, 14, 18; J. Mendlewicz, personal communication, 1990), the contextual assessment pioneered by Brown and his collaborators (16, 17, 21), and similar in-depth assessments of role loss (12). In the study of G. Brown (personal communication, September 1991), different roles for psychosocial stressors in the first and subsequent episodes were ob-

served only when severe endogenous or agitated depressions, not more minor and neurotic depressions, were included. The National Institute of Mental Health collaborative study on the psychobiology of depression provided data consistent with the current formulation and used a combined census of self- and observer ratings of the impact of psychosocial stressors and their potential role in a given affective episode (20). Patients with an "environment-sensitive" episode had had significantly fewer prior episodes (mean=3.7, SD=4.2, N=28) than those with "autonomous" episodes (mean=13.4, SD=27.4, N=35) ($p<0.05$). Bidzinska (22), Ghaziuddin et al. (18), Perris (8), and Cassano et al. (19) also found more stressors in initial episodes than in subsequent depressions.

It is remarkable that this variety of studies (with the exception of Kennedy et al. [23] and Glassner and Hal-dipur [24]), which had very different methods and assessment instruments, are all consistent in the demonstration that either more psychosocial stressors were involved in the first episode than in subsequent episodes of major affective disorder or psychosocial stressors appeared to have less impact on episodes occurring later in the course of illness, after many recurrences, than on the initial episode. While the majority of these studies were retrospective, the recent prospective study of depressive recurrences by J. Mendlewicz et al. (personal communication, July 31, 1990) also supports this interpretation. Mendlewicz et al. found more psychosocial stressors in association with the emergence of a depressive episode in subjects who had not experienced a depressive episode previously (mean=8.7) than in subjects who had prior histories of unipolar depression (mean=3.9). In the group of subjects without prior episodes, the events in the lives of the subjects who experienced a first depressive episode were more undesirable, negative, and uncontrollable than were the events of those who remained well. Psychosocial stress was thus associated with an initial episode of depression in the normal volunteers but less implicated in the recurrences.

Thus, if we accept the observations in the literature (1, 5-7) and the conclusions from the studies in table 1 (8-19) and others, psychobiological theories must deal with this transition from episodes that are triggered by psychosocial stresses to ones that are less likely to be triggered in this fashion, even though these later episodes occur in the context of increasing vulnerability to recurrence.

KINDLING ANALOGY FOR EVOLUTION TO SPONTANEOUS EPISODES

As previously discussed (2, 3), the kindling model provides an interesting but nonhomologous paradigm (i.e., kindled seizures do not clinically resemble affective illness [25]) in which events that are initially triggered begin to occur spontaneously. Following the development of amygdala-kindled seizures (which occur in response to a stimulation current that was previously

subconvulsant), a sufficient number of repetitions of full-blown seizures will eventually result in the appearance of spontaneous epilepsy, i.e., seizures in the absence of electrophysiological triggers (26-28). Thus, in this "hard-wired" electrophysiological model of amygdala-kindled seizures, there is an evolution from seizures that are triggered by exogenous stimulation to ones that occur autonomously without such stimuli. While the processes underlying the evolution of kindled seizures to spontaneous seizures are likely substantially different from those underlying the progression from stress-engendered to spontaneous episodes of affective disorders, the model presents a clear-cut example of the shift from episodes that are triggered to those that occur autonomously.

Earlier my colleagues and I (3) also discussed the potential relevance of the kindling model in helping to conceptualize processes and mechanisms underlying the initial emergence of robust behavioral phenomena in response to a stimulus that was previously subthreshold. In a parallel fashion, but in different neurochemical systems, repeated stressors (matching events) may come to evoke more robust behavioral consequences than are apparent after the initial stress or loss. While kindling represents a nonhomologous model of affective illness which can be compressed into a time frame of daily evocation of electrical events, kindling can also be elicited by more intermittent stimuli and its persistence (over months to years) fits a time frame pertinent to the affective disorders. Nonetheless, the processes involved in sensitization may be more directly analogous to those occurring in the affective disorders because of the behavioral rather than convulsive endpoints observed.

PROGRESSION OF RESPONSE TO STIMULANTS AND STRESSORS

Psychomotor stimulant-induced and stress-induced sensitization share many elements, and, in some instances, each can produce cross-sensitization to the other (29-34). Stimulant-induced behavioral sensitization also provides a homologous model for the evolution of manic symptoms because many of the progressive components of stimulant-induced mood and behavior mimic the transition from mild and euphoric mania to more severe and dysphoric mania (35) and, ultimately, to full-blown schizophreniform paranoid psychoses (36). While the mechanisms underlying stimulant-induced behavioral sensitization have not been entirely elucidated, it is increasingly recognized that activation of neurotransmitter pathways produces not only acute events associated with rapid alterations in neural firing and short-term neuronal adaptations (37, 38) but also a series of events that have much longer-lasting consequences for the organism. Specifically, the process of neuronal transmission also sets in motion intracellular changes at the level of gene transcription (39-43). One such change is the induction of a series of transcription factors, such as the proto-oncogene *c-fos*,

that subsequently alter gene expression by binding at DNA sites and inducing mRNAs for other substances that may exert effects over long time periods (days to months) (44–48). The transcription factors, such as c-fos and c-jun, are called immediate early genes because of the rapid onset and duration of their effects (minutes to hours). These transcription factors, by virtue of their acute effects, may provide the basis for a spatiotemporal cascade of events that result in more enduring neurotransmitter, receptor, and peptide changes that might provide the biochemical and anatomical basis for long-term synaptic adaptations and memory that could last indefinitely.

EFFECT OF STRESS ON GENE TRANSCRIPTION

Nakajima and associates in our laboratory (39, 40, 49) and others (42, 50–52) have demonstrated that stresses, even relatively minor ones, are capable of inducing the proto-oncogene c-fos. This can be measured by direct assessment of the Fos protein itself with antibodies (42, 50) or with Northern blot analysis to assess levels of mRNA in discrete tissues (49), or by *in situ* hybridization in which a radioactive probe binds to the mRNA for c-fos in undisturbed structures in brain slices (40, 49). This latter technique has the advantage of providing exquisite anatomical resolution of the areas involved in the c-fos induction (see figure 5 in reference 40). Electroconvulsive seizures administered through ear-clip electrodes to a mouse (40, 49) increase c-fos mRNA expression in the hippocampus, particularly the granule cells of the dentate gyrus, CA1 pyramidal cells, the ventromedial nucleus of the hypothalamus, part of the amygdaloid complex, the piriform cortex, and cerebellum. It is also noteworthy that merely applying the ear-clip for administration of sham electroconvulsive seizures was sufficient to induce low but significant increases in c-fos mRNA in the dentate gyrus, the pyramidal cells of the hippocampus, the piriform cortex, and the cerebellum (49). Even more remarkable is the induction of c-fos mRNA in hippocampal and related areas following the mild stress of an intraperitoneal saline injection. Thus, induction of transcription factors, such as c-fos, occurs rapidly and transiently in a variety of limbic system structures following seizures or even relatively mild stressors.

It is now apparent that a variety of neurochemical systems can induce c-fos in addition to their more direct and classical neurotransmitter functions. Thus, c-fos can be induced by activation of noradrenergic (α_1 , β) (53, 54), dopamine (D_1) (43, 55), acetylcholine (M_1) (56), glutamate (*N*-methyl-D-aspartate) (57), opiate, vasoactive intestinal polypeptide, and nerve growth factor (58) receptors, in addition to induction by the second messengers calcium and cyclic AMP (46, 59).

An important feature of c-fos induction is that it occurs in specific anatomical pathways in the biochemical and physiological systems that are activated. For example, the stress associated with water deprivation in-

creases c-fos in areas of the hypothalamus known to be associated with fluid and electrolyte metabolism (60). Similarly, stress involving nociceptive pathways activates appropriate substrates in the spinal cord and other sites involved in pain (42). Sagar et al. (60, 61) have shown a close parallelism between electrically stimulated cerebellar pathways mapped for metabolic activity by 2-deoxyglucose and those associated with c-fos induction. Moreover, in our laboratory Nakajima et al. (40) and Clark et al. (62–64) have demonstrated that different seizure types are associated with different patterns of c-fos induction. For example, caffeine-induced seizures induce c-fos largely in the striatum and olfactory bulb (65), while those associated with amygdala kindling are more associated with the limbic system, particularly the dentate gyrus of the hippocampus (62, 66). Cocaine-kindled seizures show a pattern involving both striatal and limbic substrates (63). Together, these data indicate the ability of c-fos induction to reflect activation of selective pathways in the CNS (40, 67) and help to address the potential problem of the apparent generality or nonspecificity of c-fos inducibility. Further specificity can be built in by the magnitude and temporal patterning of the expression of multiple transcription factors, as will be discussed.

Most pertinent to the thesis of this article, however, is the possibility that in addition to providing an anatomical marker of pathway involvement, the transient induction of c-fos (lasting several hours) and related transcription factors may also be an initial step in a cascade of neurobiological events that might have long-lasting consequences for the organism. While the long-term effects of c-fos induction have not yet been adequately elucidated, preliminary data from Sonnenberg et al. (68), Morgan and Curran (45, 46), and Crabtree (48) suggest that c-fos induction may be the first step in the induction or suppression of a variety of factors, including peptides, as reflected in the increase in mRNA for prepro-enkephalin that follows c-fos induction. In a correlative fashion, it appears that c-fos induction is sequentially followed by changes in a variety of neurotransmitters, receptors, peptides, and proteins, including nerve growth factors and other substances in the cell (figure 1). In addition, in the development of amygdala-kindled seizures, one can observe the anatomical spread of the putative "memory trace" at the level of mapping of c-fos mRNA. It is initially localized unilaterally in the piriform cortex or dentate gyrus of the hippocampus but becomes bilateral with seizure stage evolution (62). Not only is there induction of the immediate early gene c-fos, but there is also a series of longer-lasting effects on neuropeptides that include alterations in somatostatin (69–72), thyrotropin-releasing hormone (TRH) (73), enkephalin (74–76), and corticotropin-releasing hormone (CRH) (52). There also appear to be long-term decreases in dynorphin (72, 76). While the causal links between transcriptional factor (c-fos) activation and alterations in neuropeptides remain to be directly demonstrated, their temporal sequence of induction (48, 72, 77) and the occurrence in similar anatomical

areas (72) is highly suggestive. It is likely that induction of c-fos, Fos-related antigens, and other transcription factors, such as zif/268, may provide a third-messenger system (78) that then is associated with subsequent changes in gene transcription, providing longer-lasting fourth- and fifth-messenger systems as a result of prior synaptic activation.

Figure 1 illustrates, in a highly schematized fashion, that the time frame of seconds for classical pre- and postsynaptic events in neurotransmission may be only one acute phase of the process and that a variety of other intracellular events occur over much longer time domains. In the 1980s attention focused on longer-lasting but still transient changes in receptor density that occurred as an adaptation to repeated or chronic neurotransmitter exposure. The current conceptual schema suggests that, in addition, a variety of longer-term mechanisms may be brought into play through a cascade of second-messenger systems (79) and changes in protein phosphorylation (that may be involved in long-term potentiation and other types of intermediate memory) as well as the induction of tertiary transcriptional messengers, such as c-fos (45, 48, 60, 68, 78, 80). As illustrated, once mRNA for c-fos is induced, c-Fos pro-

tein is synthesized on the ribosomes of the endoplasmic reticulum. c-Fos can dimerize with itself (homodimer) or form heterodimers with other transcriptional factors, such as c-Jun, which are translocated back into the nucleus to act at AP-1 DNA binding sites that are involved in the initiation of transcription of other proteins, peptides, and growth factors. Fos and Jun interact to form a "leucine zipper" and together bind to DNA in a "scissors grip" fashion (81) more effectively than does either proto-oncogene alone. Fos is only one of many proto-oncogenes (82), and the ratio of Fos to Jun and other Fos-related antigens changes over time (45, 46). This suggests that the oncogene "milieu" conditioned by prior experience may markedly affect the subsequent alterations in gene transcription. In this fashion, specificity and selectivity of responsiveness could be exquisitely regulated according to the prior number, intensity, and "meaning" of prior experiences. Moreover, while c-jun appears to be a positive transcription factor, jun-B appears to have negative or repressive functions, further suggesting that the ratio of oncogenes and other cellular transcription factors can differentially affect the cellular output at the level of long-term changes in gene transcription. In addition to the leucine zipper motif,

FIGURE 2. Two Types of Sensitization in Affective Illness

other oncogenes interact with DNA in other fashions, such as the zinc finger [zif/268(NGFI-A)] and steroid/thyroid receptor homologues (NGFI-B) (81, 82). Complexity and selectivity of response is further suggested by the recent finding that Fos or Jun may interfere with gene induction by the glucocorticoid receptor and vice versa (83, 84). Thus, there appears to be the potential for cross-talk among transcription factors, just as there is for second-messenger systems. Moreover, the interaction between Fos and glucocorticoid receptor elements may take on special importance in the affective disorders, which are characterized by state-related changes in glucocorticoid function.

RELATIONSHIP TO RECURRENT AFFECTIVE ILLNESS

On the basis of the mechanisms just discussed one can draw a fragmentary picture of how psychosocial stressors may come to exert long-term effects on an organism. Type, magnitude, and frequency of repetition of the stressor may be critical to its long-term effects. Elsewhere my colleagues and I (85, 86) have reviewed data indicating that with cocaine-induced behavioral sensitization, the dose of cocaine (perhaps paralleling magnitude of stressors) interacts with the number of repetitions of cocaine administration (paralleling stressor repetitions) to produce an outcome matrix that affects the resulting magnitude and duration of subsequent behavioral responses. For example, repeated low doses of cocaine produce longer-lasting sensitization than does a single high dose. Intermittent doses produce more robust sensitization than chronic, continuous administration.

The quality of the stressor may similarly affect specific neural systems based not only on the type and location of short-term biochemical changes but also on the type, location, mixture, and interaction of oncogenes and transcription factors, with differential consequences for subsequent coding of long-term protein and peptide changes. Psychosocial stresses involving losses and threats of losses in a social context (table 1) may have very different cognitive, behavioral, and neurobiological consequences from stresses involving the threat of bodily injury, which may be more pertinent to the induction of syndromes such as posttraumatic stress

disorder (PTSD). However, some of the same transduction mechanisms discussed here for the encoding of long-lasting alterations at the level of gene transcription may be relevant to the development of PTSD following severe, potentially life-threatening, stressors.

Stressors related to separation, loss, and self-esteem that are associated with the onset of depressive episodes may not only play an important pathophysiological role in the triggering of an affective episode (table 1) but also, because of the neurobiological encoding of memory-like functions related to these stressors, provide a long-term vulnerability to subsequent recurrences and perhaps a mechanism for the retriggering of episodes with lesser degrees of psychosocial stress. In this fashion, one might conceptualize how more minor stresses or losses (and perhaps increasing vulnerability to more symbolic or conditioned stressors and losses) may come to play a role in the triggering of affective episodes. As in the kindling model, with sufficient repetitions of episodes, specific triggers may no longer be required to induce a full-blown syndrome.

Inherent in this concept is the notion that there are two types of sensitization mechanisms—one that is related to the stressor (relating to vulnerability) and another that occurs with the manifestation of an affective episode itself (see figure 2). That is, the experience of an affective episode and its associated neurotransmitter and peptide alterations may leave behind memory traces that predispose to further episodes, i.e., it is possible that “episodes beget episodes.” Cocaine-induced behavioral sensitization perhaps is a relevant model for this process. In this paradigm, animals show increased behavioral responses to repetition of the same dose of cocaine. It is noteworthy that this sensitization process occurs most robustly when cocaine is administered in the same environmental context in which it was previously administered (85–88), suggesting that an associative learning or conditioning component is involved. Fontana et al. (89) have recently demonstrated that this conditioned sensitization is associated with increased dopamine overflow in the nucleus accumbens measured by *in vivo* dialysis in awake, behaving animals, indicating that “psychological” phenomena such as conditioning may have neurobiological concomitants.

Most pertinent to the current argument is the finding that repeated experiences of the behavioral pathology associated with cocaine-induced hyperactivity can engage neural mechanisms that lead to increased rather than decreased responsivity in a very-long-lasting fashion (2, 35, 85, 86). An analogous endogenous process could also occur in recurrent manic or depressive episodes, i.e., the experience of an episode itself (whether or not it is psychosocially triggered) may predispose to greater reactivity or future recurrences. In this regard, it is of interest that cocaine-induced hyperactivity is associated with induction of c-fos, in this instance by a dopamine (D₁) receptor mechanism (41, 43, 55), although it remains to be demonstrated whether c-fos induction is critical to sensitization and its downstream impact on transmitter and peptide (somatostatin, dy-

norphin) regulation. In an analogous fashion, the acute neurotransmitter perturbations of an affective episode potentially involving not only D₁ mechanisms but also acetylcholine, norepinephrine, serotonin, and a variety of other systems (54–58) could, in addition to their acute and intermediate effects on the organism, also leave behind long-term residues (figure 1) as a consequence of c-fos and related transcription factor activation, leading to a cascade of long-term neuropeptide, receptor, and enzyme adaptations. Data of John et al. (90) indicate that the types of memory traces induced in learning may involve changes in the metabolic activity of tens of millions of cells in the brain of the cat, suggesting that the processes outlined in figure 1 could be occurring, in different spatiotemporal domains, in tens of millions of cells as well.

It is also likely that in some instances long-term neurobiological responses to stress may be encoded not only in biochemical processes but also in microanatomical ones. Using an organism as primitive as a snail (*Aplysia*), Kandel et al. (91, 92) have identified anatomical changes at the synapse associated with conditioning. Processes involved in long-term memory build on those used in short-term memory on the basis of an additional impact on gene expression that codes for alterations in synaptic structure as well as function. Nelson and Alkon (93) have documented changes in multiple mRNAs related to associative learning in *Hermissenda*. Even more relevant to the current argument are the recent observations of Rose et al. (94–96) following single-trial passive avoidance learning in the chick. These investigators found that long-lasting learning occurs when a chick is allowed to peck at an attractive, shiny water tube that contains a bitter substance, i.e., it subsequently avoids that tube indefinitely. This avoidance learning is encoded in a spatiotemporally arranged cascade of biochemical and microanatomical effects. These changes include early neurotransmitter and receptor alterations, translocation of protein kinase C, changes in glycogen synthesis, transient induction of c-fos and c-jun, and a variety of other longer-lasting changes that can be identified on a microscopic and electron-microscopic level, including changes in spine density, synapse number and density, and the like. In this paradigm, lesion studies additionally suggest that the gross anatomical location of the putative “memory trace” involved in this learning may (as in kindling) migrate over time, initially involving substrates in the left then right dorsal part of the brain but later localized in ventral parts of the brain, first on the right and then back on the left (96).

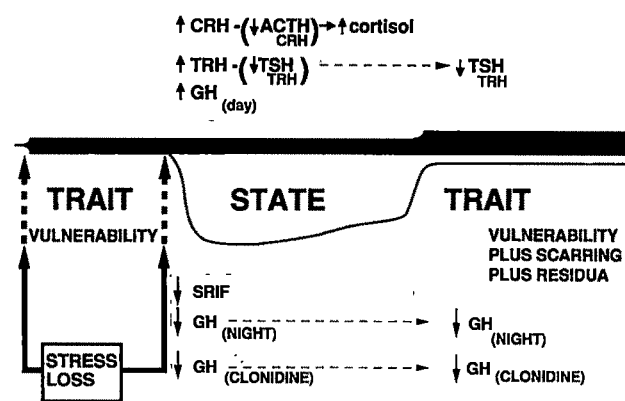

Processes of memory consolidation in the rhesus monkey (97, 98) may also differ as a function of number of learning trials, and they migrate with the passage of time. “Representational memory” may depend on limbic substrates, but “habit memory” becomes independent of these areas and may be based on striatal substrates. An evolution in the macroanatomical structures subserving single versus repeated inductions of behavioral sensitization may also occur. While a single high

dose of cocaine (40 mg/kg) engenders context-dependent sensitization that depends on the presence of the amygdala and nucleus accumbens, three high-dose injections of cocaine result in sensitization that occurs even in the absence of the amygdala (99 and unpublished data of S. Weiss et al., D. Fontana, and A. Pert). Should related mechanisms prove relevant to the neurobiology of affective disorder, they may suggest that, depending on the stage of temporal evolution in the course of affective disorders, not only might the neurochemical and microstructural synaptic mechanisms markedly differ, but the gross neuroanatomical substrates may differ as well. If this proves to be the case, it would support a reconceptualization of the neurobiology of affective disorder as a sequentially evolving process, not a static one. This would have implications not only for therapeutic studies (3) but also for clinical mechanistic studies. It suggests that the neurobiology of affective disorder is a moving target and changes as a function of the longitudinal course of illness.

Again, these conceptual vignettes are presented not with the idea that there are direct behavioral or biological homologies from kindling to the affective disorders, but only with the notion that the kind of long-lasting memory-like processes and their underlying mechanisms may provide a highly preliminary blueprint for parallel alterations in different systems that might occur with a spatiotemporal unfolding pertinent to stress reactivity and vulnerability to affective recurrence. They highlight the multiple levels of spatial and temporal complexity and the major advances in understanding the neurobiology of stress and cocaine sensitization, as well as kindling and related models of long-term plasticity. These models may also begin to provide potential candidates for the types of molecular mechanisms involved in coding the biochemical and anatomical alterations mediating the long-term changes in responsiveness. While findings from these models may be only indirectly relevant to the affective disorders, they highlight principles that may be ultimately applicable to their long-term course and treatment.

IMPLICATIONS FOR THERAPEUTICS

What are the potential implications of such long-lasting changes in both stress responsivity and episode sensitization if one assumes for the moment that the changes outlined here occur and that the details will ultimately be documented? The current formulation emphasizes that modern neuroscience can now incorporate on a more mechanistic basis older psychodynamic theories regarding a critical role of stress and loss in the pathogenesis of affective disorder in some patients. Late in the course of affective disorder, when obvious psychosocial stressors are no longer as apparent as they were earlier, the neurobiological “memory” for this vulnerability to stressors may provide a long-lasting trait marker for the individual. Just as acute seizures (presumably acting through the induction of immediate

FIGURE 3. Progression of State-Trait Phenomenon Over the Course of Affective Illness^a

^aSRIF=somatotropin release-inhibiting factor (somatostatin).

early genes) (47, 49, 62–67) are capable of producing long-lasting alterations in neuropeptides (69–76) and synaptic and neural structures characterized by dendritic sprouting (100), or even cell loss (101), it is postulated that psychosocial stressors, under appropriate circumstances, are likewise able to lead to long-lasting changes in gene expression, including more enduring alterations in neuropeptides (as summarized in figure 3) and even in neuronal microstructure, as demonstrated in other models of learning and memory (91–94). While there is ample evidence for cortisol hypersecretion in depression (perhaps driven by increased secretion of CRH [102, 103]), there is also accumulating evidence for decreases in CSF somatostatin (see reviews by Post et al. [104] and Rubinow et al. [105]). These changes and many others may reflect episode-related alterations in gene transcription (either triggered by stressors or not) that ultimately may deserve direct targeting in therapeutics. However, some alterations may represent changes that are part of the primary pathological process and require amelioration, while others may represent secondary or compensatory attempts at homeostasis and should be augmented (106).

On the basis of the sequentially evolving nature of the affective disorders, we have postulated that the pharmacoresponsivity of the disorder may differ as a function of the stage in its longitudinal course (3, 104), just as it does in kindling and other models of learning and memory. The current formulation also suggests the possibility that different psychosocial and psychotherapeutic interventions may be effective if based on the stage of illness. More specifically, while psychodynamic therapy (perhaps using “representational” or limbic memory systems [97]) may be appropriate for early, minor stress-related dysphorias or initial episodes of major depression, with repeated episodes that begin to emerge spontaneously, use of cognitive, interpersonal, and behavioral therapies may be more appropriate. If the illness is “on automatic,” in part because of many repetitions of episodes, cognitive and behavioral therapies dealing with this automaticity (targeting “habit” or po-

tentially striatal memory mechanisms [97]) may be more fruitful than dynamic therapies.

A critical role for psychopharmacological prophylaxis is also suggested by the current formulation. To the extent that “episodes beget episodes” and repetition of triggered episodes may lead to the occurrence of untriggered ones (see table 1), the dual importance of long-term prevention is reemphasized. Sensitization effects, as well as episodes and their associated morbidity, might be prevented. Biological mechanisms underlying stressor sensitization and episode sensitization in the affective disorders may be conceptualized as having the potential to carry lifelong vulnerability to recurrence.

These neurobiological possibilities square with the clinical data indicating that even several decades of successful lithium prophylaxis does not secure freedom from episode recurrence once the drug treatment is discontinued (4, 107–109). If having an episode increases the risk of subsequent episodes, this variable should be factored into recommendations for earlier initiation and longer maintenance of pharmacoprophylaxis (108). In addition to the liabilities of episode recurrence with the discontinuation of effective prophylaxis, we have identified a small series of patients who initially responded to lithium, relapsed following its discontinuation, but did not re-respond once they were restarted on lithium treatment (109). Thus, it is possible that not only may episodes engender vulnerability to recurrences, but their occurrence may also trigger new mechanisms that can overwhelm or circumvent a previously effective treatment. Similar chemotherapy-resistant processes have been described with the transition from primary-site to metastatic malignancies, which often involve the induction or suppression of additional oncogenes (110–113). Thus, the additional rationale for maintenance of long-term prophylaxis in bipolar disorders to prevent “malignant” transformation to rapid cycling or drug resistance is supported by a modicum of clinical evidence, but it needs to be further documented. Exploration of the potential consequences of failure to maintain prophylaxis is now further bolstered by the initial insights into potential neurobiological mechanisms that may convey these long-lasting vulnerabilities.

In a parallel fashion, the highly recurrent nature of unipolar affective disorder in some patients is increasingly being recognized (3, 4, 114). The long-term prophylactic studies with imipramine (115), fluoxetine (116), and maprotiline (117) not only highlight the high frequency and rapidity of unipolar depressive recurrences within a year after successful treatment of an acute episode (when active drug is replaced by placebo) but also emphasize the effectiveness of prophylaxis in substantially and significantly inhibiting these recurrences (when active drug is blindly continued). The current formulation—that having had an episode leaves behind neurobiological residues that make a patient more vulnerable to subsequent episodes—raises the question of whether earlier institution and maintenance of prophylaxis for unipolar episodes would also decrease the po-

tential for increasingly rapid recurrences, drug refractoriness (virtually unstudied), or chronic depression.

While most studies of the neurobiological concomitants of affective disorders have focused on state-related alterations in classical neurotransmitter, endocrine, and peptide substances, there is increasing recognition that some variables may remain abnormal during the remission between episodes (figure 3). In particular, it appears that a number of patients maintain a blunted thyrotropin response to TRH (118–120), continue to demonstrate sleep abnormalities (121, 122), show abnormal responses in the hypothalamic-pituitary-adrenal axis (123, 124, and F. Holsboer, personal communication), and have blunted sleep-related growth hormone secretion (125, 126). It remains to be documented which of these changes is reliable and which changes are markers of long-term vulnerability to recurrence as opposed to neurobiological “scars” representing markers of having experienced an episode of affective disorder. In either case, the current discussion provides a framework for considering alterations in gene expression as mechanisms by which these changes might arise and in some instances persist.

It is known that in the evolution of some types of cancer there is a long sequence of activation of some oncogenes and loss of other suppressor oncogenes (interacting with environmental influences and hormonal changes associated with development of the organism) which are requisite to the development and progression of tumors (110, 113, 127). This process highlights the potential roles of genetic predisposition, environmental (experiential) factors, and developmental processes (endocrine maturation, etc.) and their interactions (110) in illness evolution. Some of the principles of the development of oncogenesis that have recently been uncovered could be examined for their relevance to the evolution and unfolding of affective illness and its treatment, including the importance of prophylaxis, early intervention, combination therapies, and targeting of therapeutic approaches to the stage of illness.

The clinical data and biological vignettes presented in this article are obviously fragmentary and incomplete, providing only rough landscapes that must be brought into more detailed focus. Nonetheless, they are presented in order to anticipate the more detailed exposition of the precise neurobiological mechanisms involved in different types of learning and memory paradigms and the careful evaluation of their relevance for the longitudinal course of affective disorders. While these developments are eagerly awaited, it may nonetheless be pertinent to begin to formulate questions regarding the nature of the neurobiological changes underlying the longitudinal course of affective disorders so that appropriate studies to explore mechanisms and the impact of psychological and pharmacological interventions can be preliminarily formulated, designed, and tested.

The Psychotherapist as Witness for the Prosecution: The Criminalization of *Tarasoff*

Gregory B. Leong, M.D., Spencer Eth, M.D., and J. Arturo Silva, M.D.

The "duty to protect" doctrine heralded by the Tarasoff decision seeks to prevent physical harm to third parties by psychiatric patients. Recent court cases have mandated the testimony of a criminal defendant's psychotherapist both about the Tarasoff warning itself and about confidential treatment information that was associated with the warning. One court further ruled that some clinical sessions were not psychotherapy and therefore were not afforded the protection of psychotherapist-patient privilege. The continuing erosion of confidentiality has resulted in psychiatrists and other mental health professionals becoming prosecution witnesses at the criminal trials of their own patients.

(Am J Psychiatry 1992; 149:1011-1015)

Prior to the first decision in *Tarasoff v. Regents of the University of California* 1974 (1), psychotherapists faced no legal responsibility to other persons for the future actions of their patients. After embarking upon an unusual rehearing of that case, the California Supreme Court in 1976 issued the definitive *Tarasoff v. Regents of the University of California* decision (2), which enunciated the "duty to protect" doctrine that obligates psychiatrists and other mental health professionals to take appropriate steps to diminish the danger posed by their patients to certain third parties. Failure to discharge that duty properly, coupled with a subsequent injury to the threatened person, exposes the therapist to civil damages for malpractice. In a previous article in this journal, Mills et al. (3) recounted the details of the *Tarasoff* case and its many progeny in other jurisdictions over the ensuing decade.

In California the *Tarasoff* duty to protect can be fulfilled by any clinical intervention designed to reduce patient dangerousness, including inpatient or outpatient

treatment by pharmacologic, behavioral, and/or psychotherapeutic means. If clinical interventions are not deemed sufficient, the psychotherapist can breach confidentiality and alert the potential victim through a "Tarasoff warning." Since violence perpetrated by patients is not always preventable, the existence of a duty to protect serves as a continuing source of anxiety for the malpractice-conscious psychotherapist. Further, a patient could conceivably file a civil suit against the therapist for breaching confidentiality by warning a potential victim. A difficulty associated with duty to protect doctrines in states such as California is that the legal rules arise from case law and not statutory law enacted by the legislature. Case law, as elaborated through judicial decision, is oftentimes predicated solely on the unique facts of a particular case and may prove difficult to apply in other instances. In response to these concerns, several states have adopted statutes protecting psychotherapists from civil liability for harm inflicted by their patients if certain legally prescribed steps are taken (4). In California, for instance, psychotherapists must warn both the foreseeable victim and the police in order to enjoy protection from subsequent lawsuits (5).

Despite the widespread attention that the duty to protect and its attendant breach of confidentiality have received (6, 7), psychiatric commentators have not anticipated the use of a *Tarasoff* warning as a potent prosecutorial weapon during subsequent criminal proceed-

Received July 10, 1991; revision received Dec. 10, 1991; accepted Jan. 17, 1992. The authors thank Robert D. Goldstein, J.D., for his comments.

ings against a patient. In three recent murder cases, *People v. Clark* (8), *People v. Wharton* (9), and *Menendez v. Superior Court* (10), California courts have significantly eroded the concept of patient confidentiality and the enterprise of psychotherapy by opening psychiatric treatment to public scrutiny after the danger posed by the patient/defendant had ended.

In modern times, the patient generally has the prerogative of deciding when and with whom the contents of the psychiatric record can be shared. Related to this prerogative is (testimonial) privilege. Privilege is statutory law granting the holder of the privilege the right to prevent the person to whom confidential information was given from disclosing it in a legal proceeding (11). The California psychotherapist-patient privilege statute provides for the confidentiality of psychotherapist-patient communications in order to safeguard the therapeutic process (12). Interestingly, part of the legal rationale behind the *Tarasoff* duty involves the "dangerous patient" exception (13) to the psychotherapist-patient privilege, despite the fact that the *Tarasoff* situation did not involve a legal proceeding. All three of the cases we discuss here relied heavily on this dangerous patient exception to allow introduction of a *Tarasoff* warning as evidence into a criminal proceeding. This statute reads, "There is no privilege . . . if the psychotherapist has reasonable cause to believe that the patient is in such mental or emotional condition as to be dangerous to himself or to the person or property of another and that disclosure of the communication is necessary to prevent the threatened danger." We present brief summaries of each of these landmark cases, followed by an explanation of the implications of this legal assault on the practice of psychiatry.

CASES

People v. Clark

Mr. Clark was charged with capital murder after being accused of setting fire to the home of his former psychotherapist, causing her to suffer substantial burn injuries and causing her husband's death. A defendant convicted of capital murder faces either the death penalty or life in prison without the possibility of parole.

Defense counsel retained a clinical psychologist, among other expert witnesses, to assist in the evaluation of Clark's mental status for possible use in his defense. The clinical psychologist was confidentially retained under both the attorney-client privilege and the psychotherapist-patient privilege. During the psychological assessment, Clark told the clinical psychologist of his plan to kill two individuals—one who he believed had caused the dissolution of a previous marriage and the other who he believed had encouraged his former psychotherapist to terminate his psychotherapy. Several months later, the clinical psychologist discharged her perceived *Tarasoff* duty by having her attorney notify the identified potential victims.

Clark was eventually convicted of capital murder. During the penalty phase of the trial to determine Clark's sentence, the trial judge permitted the clinical psychologist to testify about Clark's homicidal threats. The judge allowed the *Tarasoff* warning into evidence on the basis of the dangerous patient exception to the psychotherapist-patient privilege. The judge ruled that Clark had waived his privilege by expressing the threats. Although the trial judge did not rule that Clark had waived his attorney-client privilege, the judge nevertheless accepted the clinical psychologist's testimony about the *Tarasoff* warnings. Clark subsequently received the death penalty.

On appeal, the California Supreme Court affirmed the death sentence. While the admissibility of the *Tarasoff* warnings as prosecutorial evidence was not central to the Court's legal decision, the justices did opine that once confidential information is disclosed to others (in this case, to the identified potential victims) in a non-privileged communication, it forever loses its confidential status. The Court did, however, agree with the defense contention that since the attorney-client privilege had not been waived, the *Tarasoff* warnings had been wrongly admitted into evidence. However, the Court felt that this error had only a negligible effect on the outcome, was therefore not prejudicial, and did not justify a rehearing.

People v. Wharton

Mr. Wharton and Ms. S had been cohabiting for about 1 year when Mr. Wharton sought treatment from a postdoctoral psychology intern and a psychiatrist for his anger and fear of physically harming Ms. S. During his second session with the psychologist, Wharton agreed to bring Ms. S to the next scheduled meeting in order to discuss his violent thoughts about her. Nonetheless, the psychologist telephoned Ms. S and issued a *Tarasoff* warning, telling her that she was in danger and should stay away from Wharton. Although Ms. S had previously been physically attacked and threatened by Wharton, she said that she feared being lonely and felt that if she left, Wharton would kill her anyway. About 1 week after the fourth psychotherapy session with the psychologist, Wharton killed Ms. S in their apartment.

At issue in Wharton's trial was whether the prosecutor could prove the elements of premeditation and deliberation that are needed for a first-degree murder conviction. Over defense objections, the trial judge permitted the psychologist and the psychiatrist to testify about the information obtained during their treatment of Wharton that led them to issue the *Tarasoff* warning. The judge ruled that the dangerous patient exception to the psychotherapist-patient privilege applied and permitted the psychotherapists to testify about the *Tarasoff* warning process, including all information related to the warning. In fact, the defendant's psychotherapists had joined in the prosecution's petition to be allowed to so testify.

The jury returned a verdict of capital murder. During

the sentencing phase, the prosecution relied heavily on the testimony of Wharton's psychotherapists to support the argument in favor of the death penalty, with which the jury unanimously agreed.

On appeal, the California Supreme Court affirmed the death sentence by a 4-to-3 vote. The four-justice majority found no violation of the psychotherapist-patient privilege, since the confidential communications were deemed to have become nonconfidential as a result of the *Tarasoff* warning. The Court also allowed into evidence the confidential information on which the psychotherapists based their decision to provide the *Tarasoff* warning, even though this material was not directly a part of the *Tarasoff* warning.

In *Wharton*, three California Supreme Court justices offered two separate dissenting opinions. The first argued that the majority had incorrectly interpreted the dangerous patient exception statute by ignoring the intent of the statute to avert future harm in using it to cover a danger that had already passed. The second dissenting opinion objected to the enormous discretion that the majority opinion afforded the state in introducing information beyond the confines of the *Tarasoff* warning. Prosecutors could henceforth admit into evidence all "impressions and diagnoses which prompted such warnings . . . [and] . . . statements made by the defendant himself which lead to impressions, diagnosis and conclusions by [the psychotherapists] to warn the victim." Both dissenting opinions stated the belief that a retrial was indicated because without prosecutorial use of either the *Tarasoff* warning (first dissenting opinion) or excessive amounts of confidential information beyond the *Tarasoff* warning (second dissenting opinion), the prosecution might not have been able to prove that Wharton had formed the requisite mental states (i.e., premeditation and deliberation) for first-degree murder.

Menendez v. Superior Court

Two brothers, E. Menendez and J. Menendez, were accused of murdering their parents. A couple of months later, on Oct. 31, 1989, E. Menendez met with the clinical psychologist who was treating both brothers. Because the psychologist sensed that E. Menendez might wish to confess to the killing of his parents, he arranged for his business associate, Ms. S, to be nearby so that she could call the police if trouble arose. E. Menendez stated that he and his brother had killed their parents. Fearing that J. Menendez was the more dangerous of the two brothers, the psychologist telephoned him and invited him to his office to determine his response to his brother's revelation. The psychologist asked Ms. S to eavesdrop on that session.

As a result of the Oct. 31 session, the psychologist concluded that he and his family were in danger. He telephoned his wife and told her that his patients had confessed to having killed their parents and instructed her to take their children and leave home. He also feared that Ms. S was in danger.

The psychologist concluded that the best way to reduce the danger to himself, his family, and Ms. S was to convince his patients that he was their ally and that if they continued to see him, the information they revealed "could potentially be helpful . . . in the event they were brought to trial for their parents' murder." For his own protection, he audiotaped the ensuing three sessions. On Nov. 2, he told the brothers that although the session was confidential, if they threatened him or anyone else, or if anything happened to him, the tapes would be given to the police. The majority of the third session was devoted to a discussion of E. Menendez's fear of his brother. The fourth session focused on the brothers' "family constellation," including their relationships with each other and with their parents.

During the first week of March 1990, after the psychologist and Ms. S had ended their association, Ms. S went to the police and revealed everything she had learned about the brothers. Using this information, the police obtained a search warrant for the audiotapes.

Defense counsel sought to prevent the admission into evidence of the communications to the psychologist during the four audiotaped sessions. The trial judge ruled that the contents of these four sessions were not confidential because the psychologist had made reasonable and necessary disclosures pursuant to the dangerous patient exception to the psychotherapist-patient privilege after the session of Oct. 31, 1989. On appeal, in a unanimous decision, the California Court of Appeal extended the trial court's ruling by holding both that the contents of the first two sessions were rendered nonprivileged by the dangerous patient exception and that the final two sessions were not in fact psychotherapy, so the psychotherapist-patient privilege could not apply.

DISCUSSION

In all three cases, the prosecution's access to the once-privileged and confidential psychiatric record began with a *Tarasoff* warning. In essence, once confidentiality is lost in one context, it can never be regained in another.

Clark was the first case that delineated the basis for the erosion of the psychotherapist-patient privilege. Although the psychologist had properly carried out her *Tarasoff* duty by a warning, the California Supreme Court held that its admission into the trial had been in error because it violated the attorney-client privilege under which the psychologist had also been appointed. However, this violation of confidentiality was not considered legally important to the outcome. Despite the aforementioned court viewpoint being "dicta" (expressions in the court's opinion which go beyond the facts before the court and therefore are individual views of the author of the opinion and not binding in subsequent cases [14]), the threat inherent in the *Clark* ruling lay in the likelihood that the use of a *Tarasoff* warning during trial would extend to nonforensic, clinical settings (15),

as has now been realized in the subsequent *Wharton* and *Menendez* rulings.

Wharton is important to psychiatrists and other mental health professionals because it expands the scope of confidential information that could be revealed during a trial. *Wharton* permits the courtroom disclosure of all confidential psychotherapist-patient communications that were considered by the therapist in reaching the decision to issue a *Tarasoff* warning. It can be exceedingly difficult to determine what previously confidential psychotherapist-patient information formed the basis for a *Tarasoff* warning. A psychotherapist's countertransference toward a patient who has committed a heinous crime could affect how he or she retrospectively perceives the scope of material that led to the warning. It can only be speculated what the reasons were that prompted *Wharton*'s psychotherapists to join in the district attorney's petition to allow them to testify.

A prominent concern generated by *Tarasoff* has been whether potentially violent patients would be dissuaded from seeking treatment and participating openly in sessions (16). The *Wharton* case further heightens this concern by raising the specter of the psychotherapist serving as a prosecution witness. The California Supreme Court in its majority opinion dismissed this concern as "entirely speculative." Instead, it considered public safety as its priority, citing Justice Tobriner's often-quoted comment in *Tarasoff* that "the protective privilege ends where the public peril begins." However, the *Tarasoff* danger from *Wharton* ended when Ms. S was killed.

A question that remains unanswered is how a potentially violent patient would react to the knowledge that his or her psychotherapist could become a prosecution witness. The *Menendez* case raises fears for clinicians' safety when confidentiality is breached by implementing the *Tarasoff* duty. The Appellate Court's consideration of *Menendez* was conducted independent of the Supreme Court's review of *Wharton*. What might the *Menendez* brothers have done to their therapist if *Wharton* had already been decided and they knew that their sessions would be disclosed in court?

The *Menendez* decision does not appear to lead to erosion of psychotherapist-patient confidentiality beyond that of *Wharton*. However, a noteworthy intrusion on psychiatric practice is the *Menendez* Appellate Court's determination of what constitutes psychotherapy. While the original *Menendez* court was concerned only with ruling whether confidentiality afforded by the psychotherapist-patient privilege applied to the sessions, the Appellate Court established new ground by deciding which sessions were actually psychotherapy and which were not. Such a judicial determination goes far beyond the province or knowledge of the judiciary by transgressing professional boundaries and failing to recognize the unique expertise of mental health professionals in conducting their work.

These three cases suggest that a *Miranda*-type warning, informing the patient of the existence of the *Tarasoff* duty and its potential consequences in future criminal proceedings, might be advisable when one treats

certain violence-prone patients. While *Miranda*-type warnings appear to offer a straightforward legal solution (17), ethical and clinical pitfalls remain (18).

The *Tarasoff* warning has assumed a novel legal role beyond its original intent as a single intervention designed to safeguard an endangered third party. Accordingly, determining the appropriate uses of this warning merits serious consideration. A possible approach might be for legislative action to limit or prohibit the admission into evidence in criminal trials of a *Tarasoff* warning and any related clinical material in those jurisdictions where a *Tarasoff*-type duty to protect exists. Legislative remedies to define more precisely the *Tarasoff* duty are not without debate and concern within the psychiatric profession, as they raise questions regarding the potential misuse of psychiatry to achieve social control (19, 20). Nevertheless, placing the psychotherapist in the predicament of possibly becoming a witness for the prosecution, particularly in death-penalty cases, places nonforensic psychotherapists in a precarious ethical bind. Even forensic psychiatrists accustomed to these issues have been divided over the ethical propriety of participating in capital cases, especially in the role of expert witness for the prosecution (21).

While the specific cases discussed in this article were all capital cases, their applicability in California law reaches all criminal cases. Beyond California's borders, the possibility of the prosecution's use of a *Tarasoff*-type warning in a criminal trial depends on local law. However, there is no reason to believe that the general legal principles underlying these California cases cannot be adjudicated elsewhere.

Psychiatrists and other mental health professionals, through their respective professional organizations, may wish to adopt a proactive policy of advocacy in the legislature for statutory limits on the prosecutorial use of the *Tarasoff* warning and related clinical material. In the absence of such efforts, psychotherapists will continue to be called as prosecution witnesses, with a resulting threat to their safety. Finally, the tension associated with these possibilities will likely further distance psychotherapists from treating difficult and dangerous patients. It may be acceptable to warn potential victims in an attempt to avert tragedy, but it may well prove intolerable for therapists to assume a prosecutorial role long after the danger has dissipated.

Decreased Brain Metabolism in Neurologically Intact Healthy Alcoholics

Nora D. Volkow, M.D., Robert Hitzemann, Ph.D., Gene-J. Wang, M.D.,
Joanna S. Fowler, Ph.D., Gale Burr, M.S., Kathy Pascani, M.S.,
Stephen L. Dewey, Ph.D., and Alfred P. Wolf, Ph.D.

***Objective:** The extent to which cerebral dysfunction in alcoholics is related to the direct effects of alcohol in the brain rather than to indirect mechanisms and/or alcohol withdrawal remains unclear. The purpose of this study was to evaluate whether healthy alcoholics with no evidence of alcohol-associated complications showed changes in brain glucose metabolism. **Method:** Positron emission tomography and [^{18}F]-fluorodeoxyglucose were used to measure regional brain metabolism. The study group consisted of 22 normal, healthy, right-handed volunteers and 22 neurologically intact, healthy, right-handed alcoholics tested 6 to 32 days after alcohol discontinuation. **Results:** Alcoholics showed significantly lower whole brain metabolism than normal control subjects. Normalization of regional metabolic values to the whole brain metabolic rate revealed that the left parietal and right frontal cortices were the most affected regions. Although the whole brain metabolic rate was correlated with the amount of time since alcohol discontinuation, the "normalized" decreases in left parietal and right frontal glucose metabolism were not. **Conclusions:** These findings support the contribution of the direct effect of alcohol as well as alcohol withdrawal on the changes in regional brain metabolism seen in alcoholics. They also provide evidence of cerebral changes in neurologically intact healthy alcoholics.*

(Am J Psychiatry 1992; 149:1016-1022)

Chronic excessive ingestion of alcohol is associated with cerebral dysfunction as indicated by electrophysiological (1, 2), neuropsychological (3, 4), neuro-radiological (5-11), and nuclear imaging (12-21) studies. However, the extent to which the cognitive deficits in alcoholics stem from factors other than alcohol, such as trauma, abnormal nutrition and metabolism, and/or alcohol withdrawal, is unclear (22).

Measurements of cerebral blood flow (CBF) and of brain glucose metabolism have been shown to be sensitive indicators of cerebral function (23). Multiple studies have been done to evaluate changes in CBF in chronic alcoholics (15, 18). Although there are discrepancies among investigators, most studies tend to report decreased CBF in alcoholics. The extent to which CBF changes in alcoholics reflect changes in brain function is confounded by the direct vasoactive properties of alcohol (24), which could lead to uncoupling of energy metabolism and CBF. Studies done to directly evaluate changes in brain energy metabolism in alcoholics have shown mixed results. Two positron emission tomography (PET) studies in alcoholics (19, 20) have revealed decreased brain glucose metabolism, but another study (21) revealed no such change. The disparate results reported could reflect differences in the status of the patients and/or differences in how long after alcohol withdrawal the studies were done.

The purpose of this investigation was to assess regional brain glucose metabolism in neurologically intact, medically healthy alcoholics and its relation to alcohol withdrawal. Since this investigation was carried out with two different PET cameras, a separate set of

scans of normal control subjects was run for each camera and the results are reported separately.

METHOD

Alcoholic Subjects

The group of alcoholics consisted of 22 right-handed men who fulfilled *DSM-III-R* criteria for alcohol dependence. The patients' ages ranged from 28 to 51 years, and they all had at least a 15-year history of alcohol abuse. The patients were from a Veterans Administration (VA) detoxification unit and had been detoxified 6 to 32 days before the study. At the time of admission, patients were withdrawn from alcohol with decreasing doses of chlordiazepoxide over a 72-hour period and remained in the hospital throughout the evaluation. A complete physical, psychiatric, and neurological examination, including clinical laboratory evaluation (cell blood count, blood chemistries, liver function tests, thyroid screen, urine analyses) and urine drug screen were performed to rule out medical illness and/or use of psychoactive drugs other than alcohol. All of the patients had a positive family history of alcoholism in at least one of their first-degree relatives and had an early-onset history of alcoholism.

Exclusion criteria were past or present history of drug abuse other than alcohol, past or present history of medical or neurological diseases, past or present history of psychiatric illness other than alcoholism (special emphasis was placed on excluding comorbidity with psychoses or affective illnesses; patients with scores on the Hamilton Rating Scale for Depression above 15 were excluded), past history of hepatic encephalopathy, and current seizures, delirium tremens, need of psychoactive medication (other than chlordiazepoxide), and malnutrition (body weight less than 20% of ideal body weight). Chlordiazepoxide was discontinued at least 6 days before the PET study, and PET studies were delayed until there was no evidence of signs or symptoms of withdrawal.

Normal Control Subjects

Twenty-two right-handed male volunteers 23–59 years-old were recruited for this study. They were given

the same evaluation as the alcoholics to ensure absence of medical illness. Urine screens for toxicology were performed twice during the week of the PET scan to ensure lack of use of psychoactive substances. Prospective control subjects were excluded if they had a past or present history of psychiatric, neurological, or medical disease, required medication, had a history of head injury, had a past or present history of alcohol or drug abuse, or had a first-degree relative who was alcoholic. Subjects' use of alcohol was quantitated for frequency of use, dose consumed, and pattern of use. Subjects who used alcohol only under social situations, not more than once a week, without use leading to alcohol intoxication, and not more than 4 g of alcohol per week were included in the control group. None of the alcoholic or normal control subjects were receiving any type of medication at the time of the study.

Half of the normal control subjects and half of the alcoholics were scanned by using the PET VI, and the other half were scanned by using the CTI tomograph. Table 1 provides demographic and clinical characteristics of the subjects for studies on the two tomographs.

All subjects received a neuropsychological examination. In addition, the normal control subjects and the alcoholics studied with the CTI received an magnetic resonance imaging (MRI) scan done on a GE Signa 1.5 Tesla system to exclude those with substantial structural brain abnormalities (subjects with evidence of moderate or severe cortical atrophy/and or ventricular enlargement were eliminated from the study). The MRI scans were rated blindly by three independent investigators for rate of cortical atrophy and for ventricular enlargement (0=none, 1=mild, 2=moderate, 3=severe) (interrater reliability $r=0.96$).

Scanning

The PET scans were performed for one of the studies on the PET VI tomograph in the high-resolution mode (in-plane resolution of 9 mm, full width half maximum) and for the other study on a CTI tomograph (model 931) (in-plane resolution 6 mm, full width half maximum). The PET scans were performed following an intravenous bolus injection of 5–7 mCi of [^{18}F]-fluorodeoxyglucose (FDG). All scans were done under baseline conditions (eyes open, ears unplugged) in a dimly lit room with noise kept to a minimum. Positioning of the

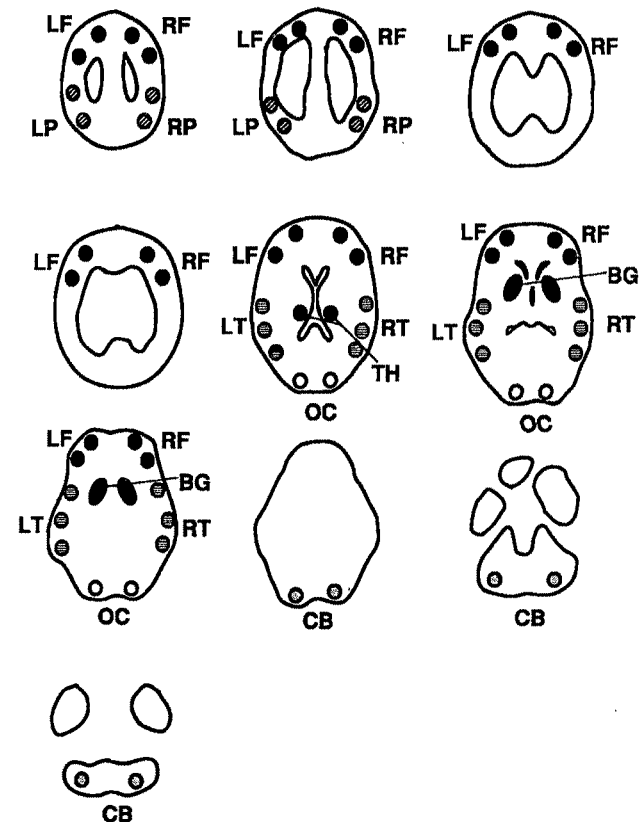

FIGURE 1. Location of Regions Sampled to Obtain Metabolic Values for 10 "Composite" Brain Regions From PET VI Images^a

^aMetabolic values of regions of interest corresponding to the same anatomical areas (shaded similarly) were averaged to obtain "composite" values. Composite values for left (L) and right (R) frontal (F), parietal (P), and temporal (T) cortices were obtained, and one value was obtained for occipital cortex (OC), thalamus (TH), basal ganglia (BG), and cerebellum (CB).

subject in the gantry was accomplished by using an individual headholder and two sets of weak laser fan beams that illuminated the head surface along the canthomeatal line and along the sagittal line, respectively. Before radiotracer injection, each subject underwent a transmission scan performed with a ring filled with germanium 68/gallium 68 to allow the subsequent emission image to be corrected for attenuation. A catheter was placed in the antecubital vein for radiotracer injection and in a dorsal hand vein for "arterialized" blood sampling (25). Arterialized blood was obtained to measure FDG, glucose, PO₂, and PCO₂. The PET scans were taken 35 minutes following injection of FDG. For the study done on the PET VI the scans were done for a total of 8 minutes; the CTI studies were carried out for 20 minutes. Metabolic "rates" were calculated as described elsewhere (25). Studies followed the guidelines approved by the human studies research committee at both our laboratory and the VA medical center, including informed consent procedures.

Image Analyses

Regions of interest were drawn directly on the PET images by using the Matsui/Hirano atlas as a reference (26). Thirty-four regions of interest were selected from the images obtained with the PET VI, which provides seven contiguous slices. Seventy-two regions of interest were selected from 10 of the 15 images obtained with

FIGURE 2. Location of Regions Sampled to Obtain Metabolic Values for 10 "Composite" Brain Regions From CTI Images^a

^aMetabolic values of regions of interest corresponding to the same anatomical areas (shaded similarly) were averaged to obtain "composite" values. Composite values for left (L) and right (R) frontal (F), parietal (P), and temporal (T) cortices were obtained, and one value was obtained for occipital cortex (OC), thalamus (TH), basal ganglia (BG), and cerebellum (CB).

the CTI. Weighted averages (to correct for difference in sizes) of the regions of interest from different slices corresponding to the same anatomical areas were computed to obtain metabolic values in 10 "composite" brain regions. Figures 1 and 2 show the location of the regions of interest sampled and the regions of interest that were included to obtain the 10 "composite" brain regions for the PET VI and for the CTI images, respectively.

A mean value of whole brain glucose metabolic rate was obtained by averaging the metabolic rates from all the pixels within the skull. "Relative" measures of regional brain metabolism were obtained by using the ratio of the metabolic value in the "composite" brain regions to the metabolic value for the whole brain. Differences in absolute and relative brain glucose metabolism for the "composite" brain regions between normal control subjects and chronic alcoholics were analyzed by using two-tailed Student's *t* test separately for the studies done on both tomographs. Because of the multiple comparisons involved in the analyses, differences were considered significant only if they were

FIGURE 3. Brain CTI Metabolic Images in a Normal Control Subject and an Alcoholic Subject Tested 2 Weeks (2W) After Last Use of Alcohol^a

^aNotice the decreased cortical metabolic activity in the alcoholic.

significant ($p < 0.05$) in both studies. Since the normal control subjects were younger (mean=32 years, SD=12) than the alcoholic patients (mean=39 years, SD=7) in the study done with the CTI, the effect of aging on brain metabolism was evaluated in this group of subjects by obtaining the regression equation for global brain metabolism and age in the normal control subjects and then obtaining the predicted metabolic values for subjects of that age among the alcoholics. The differences between the observed and the predicted metabolic values were then tested for significance with one-sample two-tailed t tests. This analysis was used because the covariate analysis was inappropriate due to differences in the regression lines between normal subjects and alcoholics. To evaluate the contribution of alcohol withdrawal to the metabolic changes found in the alcoholic subjects, we performed a correlational analysis between the variables that were found to be significantly different between normal subjects and alcoholics and the days since last alcohol use.

RESULTS

Neuropsychological evaluation of the alcoholic subjects did not reveal evidence of major cognitive impairment in these patients. The only tests on which alcoholics performed significantly worse than normal subjects were the Trailmaking test (27), the Symbol Digit Modalities (28), and the Stroop (29). The 11 alcoholics for whom MRI scans were obtained showed evidence of mild cortical atrophy (mean=1.1, SD=0.7) and mild ventricular enlargement (mean=0.9, SD=0.8), but the 11 normal subjects for whom scans were obtained did

FIGURE 4. Individual Values for Whole Brain Metabolism of Normal Subjects and Alcoholics Studied With PET VI and CTI

not (cortical atrophy mean=0.2, SD=0.5; ventricular enlargement mean=0.3, SD=0.05).

Alcoholics had significantly lower whole brain metabolism than normal control subjects. Figure 3 shows the brain metabolic image for a normal control subject and for an alcoholic, and figure 4 shows the individual values for whole brain metabolism for the normal subjects and for the alcoholics. The two studies showed whole brain metabolism to be significantly lower in alcoholics. For the PET VI study, normal subjects had a mean of 31.8 $\mu\text{mol}/100 \text{ g/min}$ (SD=3) and alcoholics had a mean of 28.7 $\mu\text{mol}/100 \text{ g/min}$ (SD=3) ($t=2.3$, $df=20$, $p < 0.05$). For the CTI study, normal subjects had a mean of 37.6 $\mu\text{mol}/100 \text{ g/min}$ (SD=3) and alcoholics had a mean of 31.2 $\mu\text{mol}/100 \text{ g/min}$ (SD=4) ($t=3.88$, $df=20$, $p < 0.001$). The difference in brain metabolic activity between the groups remained after correcting for age ($t=-3.63$, $df=10$, $p < 0.005$). Differences in regional absolute metabolic values between nor-

mal subjects and alcoholics ranged from 7% to 17% for the PET VI and from 14% to 25% for the CTI and were significant across most brain regions (table 2). The lower metabolic values obtained with the PET VI compared with the CTI are consistent with the lower spatial resolution of the former tomograph (30) and with the smaller volume of the regions of interest used to analyze the images from the CTI (figures 1 and 2).

Analyses of the normalized metabolic rates ("relative" measures) revealed that in the alcoholics certain brain regions were consistently lower than average. Figure 5 shows the average "relative" values for different brain regions in normal control subjects and in alcoholics for the PET VI and the CTI. Studies on both tomographs showed that the right frontal and left parietal cortices of alcoholics had disproportionately lower glucose metabolic rates than other parts of the brain. In the PET VI study, for the right frontal cortex, normal subjects had a mean of 1.11 (SD=0.04) and alcoholics had a mean of 1.05 (SD=0.06) ($t=2.51$, $df=20$, $p<0.02$) and for the left parietal cortex, normal subjects had a mean of 1.09 (SD=0.05) and alcoholics had a mean of 0.98 (SD=0.07) ($t=3.52$, $df=20$, $p<0.002$). In the CTI study, for the right frontal cortex, normal subjects had a mean of 1.46 (SD=0.05) and alcoholics had a mean of 1.35 (SD=0.10) ($t=3.02$, $df=20$, $p<0.01$) and for the left parietal cortex, normal subjects had a mean of 1.37 (SD=0.06) and alcoholics had a mean of 1.28 (SD=0.06) ($t=3.24$, $df=20$, $p<0.005$).

The correlation analyses showed a significant correlation between whole brain metabolism and number of days since last alcohol use. In the PET VI study, $r=0.63$, $df=10$, $p<0.05$, and in the CTI study, $r=0.83$, $df=10$, $p<0.01$ (figure 6). In contrast, the "relative" values for the right frontal and left parietal cortices were not correlated with the number of days since last alcohol use (PET VI right frontal cortex, $r=0.32$, $df=10$, n.s.; PET VI left parietal cortex, $r=0.20$, $df=10$, n.s.; CTI right frontal cortex, $r=0.27$, $df=10$, n.s.; CTI left parietal cortex, $r=0.37$, $df=10$, n.s.).

DISCUSSION

This study documents decreased brain glucose metabolism in neurologically intact otherwise healthy alcoholics. The decrease in whole brain metabolism related to the number of days since last alcohol use, suggesting that it represents, in part, a cerebral response to alcohol discontinuation. It is interesting to note that the brain metabolic changes associated with alcohol discontinuation occurred in the absence of signs and/or symptoms of alcohol withdrawal, suggesting that the cerebral response to alcohol withdrawal extends beyond the time period when the symptoms of withdrawal occur. The effects of alcohol withdrawal on brain function have been documented in both animals and humans (1) and could account for some of the brain structural recovery seen in alcoholics after 1 month of abstinence (8–10) as well as the increases in CBF seen in alcoholics after protracted abstinence (16). Brain metabolic changes during withdrawal could represent fluid and electrolyte changes (31), neurotransmitter adaptation (32, 33), and/or remyelination and neuronal plasticity (34). Evaluation of the degree of brain metabolic recovery in alcoholics after protracted withdrawal requires a prospective longitudinal study.

The decreases in whole brain metabolism are in agreement with previous studies showing consistent reductions in CBF in alcoholics (15, 18, 35). However, unlike the previous studies, in which the reductions in CBF were found to be related to neurological impairment and brain atrophy, this study demonstrates cerebral metabolic deficit in alcoholics with no neurological symptoms and with minimal or no brain morphological changes.

In addition, this investigation shows relative decreases in metabolism in the left parietal and right frontal cortices of alcoholics, with the parietal cortex showing the greatest decrease in metabolism. These regional findings are independent of the amount of time since last alcohol use and are identical to those reported in a

FIGURE 5. Relative Metabolic Values for Different Brain Regions in Normal Subjects and Alcoholics Studied With PET VI and CTI^a

^aROI=region of interest, LF=left frontal, RF=right frontal, LP=left parietal, RP=right parietal, LT=left temporal, RT=right temporal, OC=occipital, TH=thalamus, BG=basal ganglia, CB=cerebellum. Both studies showed that the left parietal and the right frontal cortices were the most affected regions in the alcoholics.

previous study done in a group of neurologically impaired alcoholics (20), suggesting that they result from the direct effects of alcohol on brain tissue rather than from alcohol-induced medical complications. Although the localization of the anatomical and/or functional deficits in the brain of alcoholics differs among investigators, the parietal and frontal cortices are consistently reported as being affected to a greater degree than other brain structures (1). This study reports regional later-

FIGURE 6. Correlation Between Number of Days Since Last Alcohol Use and Whole Brain Metabolism in Normal Subjects and Alcoholics Studied With PET VI and CTI

alization for the metabolic deficits in alcoholics (the right frontal cortex was more impaired than the left and the left parietal cortex more than the right), but it does not support the contention that the right hemisphere is more vulnerable to the toxic effects of alcohol than the left (1). Even though we excluded patients with evidence of moderate to severe cortical atrophy, more alcoholics than normal subjects showed evidence of mild degrees of morphological brain changes. The extent to which these structural changes contribute and/or reflect the dysfunction leading to decreased brain metabolism cannot be inferred from this investigation. Nor can this study rule out the possibility that the brain metabolic changes reported in these alcoholics antedated their use of alcohol.

This study shows that decreased brain metabolism in alcoholics is in part related to alcohol withdrawal and that brain metabolic dysfunction in alcoholics is not limited to neurologically affected patients.

Are There Clinical Differences Between Familial and Nonfamilial Alzheimer's Disease?

Daniel J. Luchins, M.D., Donna Cohen, Ph.D., Patricia Hanrahan, Ph.D.,
Carl Eisdorfer, Ph.D., M.D., Gregory Paveza, Ph.D., J. Wesson Ashford, M.D., Ph.D.,
Philip Gorelick, M.D., M.P.H., Robert Hirschman, Ph.D., Sally Freels, Ph.D.,
Paul Levy, Sc.D., Todd Semla, Pharm.D., and Helen Shaw, M.A.

Objective: The purpose of the study was to determine whether there are differences in clinical characteristics in two groups of patients with Alzheimer's disease, those reported to have a family history of dementia and those without a family history of dementia. **Method:** Using a data set from an Alzheimer's disease patient registry, funded as part of a National Institute on Aging cooperative agreement, the authors made comparisons of sociodemographic and clinical variables in a group of 462 patients with Alzheimer's disease, 172 reported to have at least one first-degree relative with dementia and 290 classified with no family history. **Results:** Patients with a presumptive family history differed from those without a family history in two ways: the course of dementia was described as having a fast rather than a slow progression from onset of symptoms to diagnosis, and caregivers reported a higher prevalence of family history of psychiatric disorders. There were no significant differences in age at onset, duration, female gender, aphasia and apraxia, handedness, family history of Down's syndrome, or number of children, brothers, and sisters. **Conclusions:** The association of faster course and family history of psychiatric disorders in the patients with a family history of dementia is consistent with the hypothesis of heterogeneity, but the overall results could also be explained by a genetic-environmental model of Alzheimer's disease.

(Am J Psychiatry 1992; 149:1023-1027)

Since the possible role of heredity in the etiology of Alzheimer's disease was proposed by Flügel (1), there has been growing evidence for genetic contributions to the etiology of the disease. A higher prevalence of dementia among first-degree relatives of patients has been reported in most but not all population and case-control studies (2, 3). Numerous families with multiple members afflicted with Alzheimer's disease have been studied, and although an autosomal dominant form of Alzheimer's disease is supported by most of these family studies, others suggest polygenetic/multifactorial inheritance (2, 4). There is also evidence for genetic heterogeneity in familial Alzheimer's disease, with genes

on chromosome 21 implicated in early-onset and genes on chromosome 19 implicated in late-onset forms of the disease (5, 6).

The age-dependent onset of Alzheimer's disease has led to the suggestion that most cases of the disease are familial, with the argument that many cases of familial Alzheimer's disease are incorrectly classified as nonfamilial or sporadic because older relatives of probands either are not evaluated adequately or die before growing old enough to be at risk (7, 8). However, several investigators have argued that the occurrence of familial Alzheimer's disease does not negate the role of environmental causes in some or most cases of Alzheimer's disease (2, 9). Head injury, infectious agents, environmental toxins, and advanced maternal age have all been implicated as factors linked to Alzheimer's disease (2, 9-15).

A few investigators have looked for clinical differences in patients with familial and sporadic Alzheimer's disease to test the hypothesis of heterogeneity in the etiology of the disease; that is, clinical features of familial Alzheimer's disease would distinguish it from nonfamilial Alzheimer's disease if they represent two different diseases. However, results have been inconsistent.

Breitner and Folstein (16) found that relatives of Alzheimer's disease probands with aphasia, apraxia, or agraphia had a 50% risk of developing Alzheimer's disease, while relatives of probands without such symptoms did not have a high risk. Mohs et al. (17) observed that the morbid risk of Alzheimer's disease in first-degree relatives of patients was 46% by 86 years of age. Although this series of Alzheimer's disease probands was not selected for aphasia and apraxia, only 6% did not have these symptoms. Knesevich et al. (18), as well as Edwards et al. (19), have not replicated the predictive value of aphasia.

At least two groups have reported that patients with familial Alzheimer's disease had an earlier age at onset than patients with the nonfamilial form of the disease; however, others have not replicated the simple association between familial Alzheimer's disease and age at onset (19–21). Results of several studies indicate that there are early-onset and late-onset forms of familial Alzheimer's disease and that age at onset is specific for different families (2, 7, 22–24).

The availability of a large pool of dementia patients in an Alzheimer's disease patient registry provided a research opportunity to select patients with Alzheimer's disease in order to analyze clinical differences between familial and nonfamilial forms of the disease. The objectives were to determine if earlier age at onset, faster course, aphasia, apraxia, female gender, history of Down's syndrome, and other reported factors differentiated the two groups and to test for other clinical differences in patients.

METHOD

Subjects

The subjects for this analysis were patients with Alzheimer's disease selected from an Alzheimer's disease patient registry known as the Prototype Alzheimer's Collaborative Team. The Prototype Alzheimer's Collaborative Team was established to study the feasibility and costs of establishing and operating a multisite registry for research on Alzheimer's disease and other dementias. Methods and procedures for case ascertainment, case enrollment, and data management, as well as a sociodemographic profile of the registry population, have been described (25).

Briefly, the Prototype Alzheimer's Collaborative Team consists of a Data Coordinating and Analysis Center at the University of Illinois at Chicago that registered patients diagnosed at six medical sites. Four were specialized Alzheimer's disease clinical programs: the Memory Disorders Clinic, Mount Sinai Hospital and Medical Center, Miami Beach; the Memory Disorders Clinic, the University of Miami, Jackson Memorial Hospital; the Regional Alzheimer's Disease Center, Southern Illinois University School of Medicine, Springfield; and the Alzheimer's Disease Center, Michael Reese Hospital and Medical Center, Chicago. Two were specialized

geriatric clinical programs: the Geriatric Clinic at the University of Chicago School of Medicine and the Geriatrics Institute, University of Wisconsin-Milwaukee Clinical Campus.

The Prototype Alzheimer's Collaborative Team contains diagnostic, psychosocial, and sociodemographic information on a total of 1,402 patients with Alzheimer's disease and related dementias diagnosed between 1987 and 1989. Enrolled patients were 40 years and older and living in the community at the time of diagnosis. The minimum enrollment criterion was a clinical diagnosis of dementia with documentation from physical, psychiatric, neurological, and psychological examinations. A total of 671 patients met diagnostic criteria for Alzheimer's disease. Most were diagnosed according to *DSM-III-R* or the criteria of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (26), and 90% of patients were diagnosed with both criteria. A few patients were diagnosed according to *DSM-III*.

We analyzed clinical characteristics of those 462 Prototype Alzheimer's Collaborative Team patients who met the criteria for probable Alzheimer's disease of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association, *DSM-III-R* criteria for Alzheimer's disease, or *DSM-III* criteria for primary degenerative dementia and who also were reported to have either a family history or no family history of dementia. A total of 172 patients with at least one first-degree relative (i.e., parent, child, or sibling) with dementia were classified as having a family history. The remaining 290 patients with no family history were classified as suspected of having no family history. Patients with Alzheimer's disease with a family history in only second-degree relatives ($N=27$) or with an unknown family history ($N=182$) were excluded from the analysis.

The case enrollment form contained data on family history of dementia, other psychiatric disorders, other neurological disorders, and Down's syndrome. The specific questions on family history of dementia were, "Is there a family history of dementia?" and "Specify the relationship to patient." Data coded reflected results of clinical interviews with primary caregivers, 90% of whom were spouses or first-degree relatives and 10% of whom were in-laws or other relatives.

Clinical Variables

The following groups of variables from the Prototype Alzheimer's Collaborative Team case enrollment form were used in this analysis: sociodemographic information; clinical diagnostic data, including the results of the medical, psychiatric, and neurological examinations; ratings of functional impairment and mental status at diagnosis; and results of patient CT scans and magnetic resonance imaging (MRI) at diagnosis. The format for recording specific clinical diagnostic data on the case

TABLE 1. Characteristics of 462 Patients With Probable Alzheimer's Disease With or Without a Family History of Dementia

Item	Family History (N=172)				No Family History (N=290)			
	Mean	SD	N	%	Mean	SD	N	%
Age (years)	74.0	6.9			74.9	8.4		
Men			72	41.9			90	31.0
Women			100	58.1			200	69.0
Education (years)	12.0	3.4			11.4	3.6		
Mini-Mental State score	16.0	7.4			15.0	7.5		

enrollment form was as follows: 1) seven items describing patient behaviors that precipitated the diagnostic workup, 2) a 16-item checklist of psychiatric symptoms, 3) a 26-item checklist of medical conditions, 4) a 24-item checklist of neurological symptoms, 5) a six-item checklist of impairments in activities of daily living, 6) an eight-item checklist describing findings from CT and MRI, and 7) the Mini-Mental State examination score (27).

Data Analysis

Data were analyzed comparing demographic variables in the groups with family histories and no family histories of dementia, as well as several clinical characteristics previously reported to be associated with familial Alzheimer's disease, including age at onset, duration, rapidity of progression, handedness, female gender, and the presence of aphasia or apraxia. We also examined conditions reported to occur with higher frequency in the families of individuals with Alzheimer's disease, including Down's syndrome (28) and psychiatric disorders (29). Furthermore, because of suggestions that familial forms of dementia such as Huntington's chorea might be associated with higher rates of fertility (30), we compared the number of children of patients with Alzheimer's disease in each group.

Parametric variables were analyzed with the Student's *t* test between groups with no family histories and family histories. For categorical data a 2x2 Yates's-corrected chi-square with one degree of freedom was used, except when cells were less than five, in which case a Fisher's exact probability test was calculated. A Bonferroni correction (31) was used to adjust for the multiple comparisons of patient variables.

RESULTS

Demographic characteristics of the groups with or without presumptive family histories of dementia are shown in table 1. There were no significant differences in age, gender, education, or severity of cognitive impairment according to the Mini-Mental State score. Table 2 presents the results of analyses of factors previously reported to be associated with familial Alzheimer's

TABLE 2. Clinical Factors Associated With Familial Alzheimer's Disease in 462 Patients With Probable Alzheimer's Disease With or Without a Family History of Dementia

mer's disease. Two significant differences emerged. An increasing rate of decline, in contrast to a gradual change from onset of symptoms to diagnosis, occurred more frequently in the group with a family history of dementia than in the group with no family history (76.7% versus 56.2%, *p*=0.004). Family history of psychiatric disorders was more prevalent in the group with a family history than in the group with no family history (18.6% versus 7.2%, *p*=0.0009). There were no significant differences in age at onset, duration, female gender, aphasia, apraxia, handedness, family history of Down's syndrome, or number of children, brothers and sisters. No significant differences emerged for any of the remaining clinical diagnostic variables.

DISCUSSION

Only a few clinical characteristics differentiated patient groups with presumptive familial and nonfamilial Alzheimer's disease. Early age at onset, duration, female gender, the presence of aphasia or apraxia, handedness, family history of Down's syndrome, and the number of children, brothers, and sisters did not distinguish the two groups of patients with Alzheimer's disease. Our results are consistent with the recent findings of Edwards et al. (19), who studied 151 index patients, 84 of whom had at least one relative with dementia. The lack of differences in both of these studies suggests that there is a similar clinical presentation in familial and nonfamilial Alzheimer's disease.

The major limitation of this study affecting the interpretation of our results is the possibility of classification errors in the accuracy of the diagnosis of Alzheimer's disease registry patients and the family history groupings. Since classification errors favor the null hypothesis unless a systematic bias is operating, misclassifications

increase the probability of not finding significant differences (19).

The diagnosis of Alzheimer's disease and related dementias in the Prototype Alzheimer's Collaborative Team registry was made by clinical staff at six clinical sites participating in a study of case ascertainment, case enrollment, and data management problems associated with developing and implementing a large-scale, multisite dementia registry. To reduce the impact of variability among clinicians, we restricted our analysis group to individuals who met *DSM-III-R* criteria for Alzheimer's disease, National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association criteria for probable Alzheimer's disease, and *DSM-III* criteria for primary degenerative dementia.

We classified patient groups by the available history of first-degree relatives who had dementia, and both the underreporting of dementia and the reporting of dementias other than Alzheimer's disease could cause classification errors. Although Alzheimer's disease is the most common cause of dementia, it is likely that some of the individuals with a family history described in this study had first-degree relatives with dementia that was not Alzheimer's disease.

The more rapid rate of change from onset of dementia symptoms to diagnosis, which distinguished the group with a family history, refers to an average period of 4.1 years in the group with a family history and 3.3 years in the group with no family history. This difference was only marginally significant with the Bonferroni correction ($F=7.10$, $df=1, 460$, $p=0.007$). Our results are consistent with the more rapid progression to death in familial Alzheimer's disease reported by Heston et al. (28). However, evaluating an increasing rate of decline may be a difficult clinical judgment, especially in the absence of specific criteria. It might also be confounded by a clinician's knowledge of the patient's family history and frequency of patient visits.

The higher frequency of psychiatric illness in familial Alzheimer's disease is consistent with the work of Martin et al. (29), who are the only others we know who have reported a greater occurrence of psychiatric illness in relatives of patients with Alzheimer's disease. However, they did not distinguish between patients with Alzheimer's disease with or without family histories of dementia. It is possible that there was a response bias in Prototype Alzheimer's Collaborative Team patients in which more family information might have been available for probands with a family history than for probands with no family history, leading to the documentation of other disorders at a higher rate.

Although the average age at onset was not significantly different between our two patient groups, this result might be expected if age at onset is specific for different families. Intensive study of our Prototype Alzheimer's Collaborative Team probands with standardized pedigrees and validation of Alzheimer's disease in first-degree relatives may be needed to rigorously test for clinical differences and the hypothesis of hetero-

geneity. Our findings of a more rapid course and a family history of psychiatric problems in familial Alzheimer's disease are not inconsistent with the hypothesis of heterogeneity and deserve further study.

In summary, our patients with family histories and no family histories of Alzheimer's disease appear to be largely clinically indistinguishable, not unlike other neuropsychiatric disorders, e.g., Charcot-Marie-Tooth disease, olivopontocerebellar ataxia, torsion distress, and schizophrenia (2). One explanation for these findings could be a genetic-environmental model of Alzheimer's disease that does not require clinical differences between patients with a family history and those with no family history, but only etiological differences (19). Thus, genetic factors, environmental exposures, or a combination could trigger the onset of Alzheimer's disease and its clinical symptoms.

Bright Light Treatment of Behavioral and Sleep Disturbances in Patients With Alzheimer's Disease

Andrew Satlin, M.D., Ladislav Volicer, M.D., Ph.D., Virginia Ross, Ph.D.,
Lawrence Herz, M.D., and Scott Campbell, Ph.D.

Objective: The authors tested the hypothesis that evening bright light pulses would improve sleep-wake patterns and reduce agitation in patients with Alzheimer's disease who have severe sundowning (a syndrome of recurring confusion and increased agitation in the late afternoon or early evening) and sleep disorders. **Method:** Ten inpatients with Alzheimer's disease on a research ward of a veterans' hospital were studied in an open clinical trial. All patients had sundowning behavior and sleep disturbances. After a week of baseline measurements, patients received 2 hours/day of exposure to bright light between 7:00 p.m. and 9:00 p.m. for 1 week. During the baseline week, the treatment week, and a posttreatment week, patients were rated by nurses for agitation, sleep-wake patterns, use of restraints, and use of prescribed-as-needed medication. On the last 2 days of each week, patients wore activity monitors. Activity counts were analyzed for circadian rhythmicity. **Results:** Clinical ratings of sleep-wakefulness on the evening nursing shift improved with light treatment in eight of the 10 patients. The proportion of total daily activity occurring during the nighttime decreased during the light-treatment week. The relative amplitude of the circadian locomotor activity rhythm, a measure of its stability, increased during the light-treatment week. More severe sundowning at baseline predicted greater clinical improvement. **Conclusions:** Evening bright light pulses may ameliorate sleep-wake cycle disturbances in some patients with Alzheimer's disease. This effect may be mediated through a chronobiological mechanism.

(Am J Psychiatry 1992; 149:1028-1032)

Behavioral disorders in patients with Alzheimer's disease markedly increase the burden of their caregivers. Sleep disturbances in particular and agitation, restlessness, and pacing more generally often cause caregiver stress and burnout and may precipitate institutionalization of the patient (1). "Sundowning," a syndrome of recurring confusion and increased agitation in the late afternoon or early evening, is common among patients with Alzheimer's disease in nursing homes (2). Neuroleptic medications are frequently prescribed for behavioral disorders in demented patients, but the

available evidence suggests that they are more effective than placebo alone in only 18 of 100 treated patients (3). In addition, neuroleptic use in demented patients is commonly associated with side effects that may lead to worsening of behavior and even of cognition (1, 4).

Fragmented sleep-wake cycles and sundowning are characterized by inappropriately timed rest and activity, suggesting that these syndromes may be mediated by abnormalities of the circadian timekeeping system in Alzheimer's disease. The circadian locomotor activity rhythm was found to have a lower amplitude and delayed acrophase (the time of peak daily activity) in patients with Alzheimer's disease than in healthy elderly control subjects in one study (5). The hypothesis of a disordered circadian pacemaker in some patients with Alzheimer's disease is supported by chronobiological studies of sleep and endocrine measures (6, 7) and by neuropathological studies reporting cell loss in the suprachiasmatic nucleus of the hypothalamus (8). However, the circadian rhythm of core body temperature may remain intact in Alzheimer's disease, suggesting that manipulation of the circadian system may still be possible even in demented individuals (9).

Investigators have found that properly timed bright

Presented at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received April 16, 1991; revision received Dec. 18, 1991; accepted Jan. 17, 1992. light exposure may induce phase shifts of the circadian pacemaker and may augment the amplitude of the circadian rhythm (10). An association between light exposure and behavioral disorders in Alzheimer's disease is suggested by the finding that patients with Alzheimer's disease living at home were exposed to significantly less bright light than healthy control subjects (11) and by a report of an apparent increase in sundowning behavior in nursing home patients during the winter months (12). Bright light treatment improved the sleep efficiency of normal elderly subjects with sleep maintenance disturbance in a recent study (13), and some demented patients with sleep-wake disturbances improved with phototherapy in two other studies (14, 15).

The present study sought to test the hypothesis that bright light pulses would reduce agitation and improve the sleep patterns of patients with Alzheimer's disease.

METHOD

Ten inpatients (nine men, one woman; mean age=70.1 years, SD=5.1) on the dementia study unit of a veterans' hospital were studied for 3 weeks. All met *DSM-III-R* criteria for primary degenerative dementia and National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association criteria for Alzheimer's disease (16) (mean age of onset=60.4 years, SD=8.1), and all were moderately to severely demented. The mean duration of their illness was 9.3 years (SD=6.7), their mean Mini-Mental State Examination (17) score was 0.6 (SD=1.1), and their mean Activities of Daily Living (18) score was 5.3 (SD=0.8) (the range of scores on this scale is 0–6, and higher scores indicate more impairment). Patients were identified by nursing staff as sundowners according to the following definition of this syndrome: the recurrent appearance or exacerbation of behavioral disturbances such as agitation, pacing, restlessness, yelling, or shouting in the afternoon or evening. Most of the patients began pacing or yelling between 2:00 p.m. and 4:00 p.m. Patients also exhibited sleep disturbances characterized by frequent daytime napping and nighttime awakenings. None of the patients had any substantial intercurrent medical illnesses, and none had substantial cataracts. Eight of the 10 patients were taking standing doses of neuroleptic medication, one was taking regular doses of diphenhydramine, and one was not taking any regular psychotropic medication. All 10 had prescriptions for as-needed neuroleptic or benzodiazepine medication. Written informed consent was obtained from relatives in accordance with standard hospital practice.

Nurses performed daily ratings each shift (day, evening, and night) for agitation and sleep-wakefulness disturbances on a 0–3 scale (0=none or minimal, 1=mild, 2=moderate, 3=severe). Higher scores for sleep-wake cycle disturbances represented more time awake during the night or more time asleep during the day or

evening. Scores for each shift represented ratings for the entire 8-hour period. The use of restraints (0=none, 1=one physical restraint such as a posey, geri-chair, bed rails, or hand mitts; 2=two or more forms of physical restraint) and of prescribed-as-needed medication (0=none, 1=one administration, 2=two or more administrations) were recorded for each shift. Locomotor activity was recorded for 48 hours at the conclusion of each study week by using a portable piezoelectric activity monitor with solid-state memory. The monitor was placed in the pocket of a vest worn over the patient's clothing and positioned at waist level.

During each evening of week 2 between 7:00 and 9:00 p.m., patients received 2 hours of exposure to approximately 1500–2000 lux while seated in a geri-chair facing the light box and restrained by a tray. The light box consisted of three U-shaped fluorescent bulbs (Phillips FB40/CW). Medication changes were not permitted during the 3 weeks of the study.

Nonparametric tests (Friedman's analysis of variance and Wilcoxon matched-pairs test) were used to compare weekly summed ratings of individual clinical measures over the 3 weeks of the study (baseline, treatment, and posttreatment). Relationships between baseline predictors of response and treatment effects were analyzed by using Pearson correlation coefficients. Locomotor activity data were analyzed for percent of activity for each daily shift. A cosinor analysis (19) was used to calculate the following circadian rhythm measures in the raw activity data: mesor (mean daily activity level), amplitude, acrophase, and period. Relative amplitude was calculated as the ratio of the circadian amplitude to the mesor in order to correct for differences in magnitude of the activity counts. Interdaily stability and intradaily variability also were calculated, as described by Witting et al. (20).

RESULTS

Clinical ratings of sleep-wakefulness on the evening shift improved with light treatment in eight of the 10 patients. The mean score of all 10 patients declined from 6.2 at baseline to 3.0 during the treatment week and further declined to 2.3 during the posttreatment week ($\chi^2=7.35$; $df=2$; $p=0.03$, Friedman analysis of variance [ANOVA]; for week 1 versus week 2, $z=-2.04$, $p=0.04$; for week 1 versus week 3, $z=-2.31$, $p=0.02$, Wilcoxon matched-pairs signed-ranks test). This finding was supported by some of the objective measures obtained from the activity monitor data (tables 1 and 2). Intradaily variability of the activity monitor counts (a measurement of the combined severity of daytime napping and nighttime wakefulness) decreased during week 2 in nine of the patients, although it returned to baseline at week 3 (mean for week 1=1.04; mean for week 2=0.71; mean for week 3=1.06; $F=3.87$, $df=2, 26$, $p=0.03$). Interdaily stability did not change. Percent of nocturnal activity (the proportion of total daily activity counts occurring from 11:00 p.m. through 7:00 a.m.) decreased from baseline to the light-

^aImprovement is indicated by an increase in the relative amplitude and by a decrease in all other measures.

treatment week in nine patients (mean for week 1=18.4% versus mean for week 2=11.6%; $t=2.84$, $df=9$, $p=0.02$) and also increased during week 3 (mean=17.1%), although this change was not statistically significant. According to the results of the cosinor analysis, cosinor fits were statistically significant for all patients during each study week. The relative amplitude of the rest-activity circadian rhythm increased from baseline to the light-treatment week in seven patients (mean for week 1=0.65 versus mean for week 2=0.90; $t=2.69$, $df=9$, $p=0.02$). The mesor and the period did not change. The locomotor activity acrophase shifted earlier by about an hour from baseline to weeks 2 and 3 (4:15 p.m. to 3:23 p.m. to 3:21 p.m.), but this change was not statistically significant.

Clinical ratings of agitation, use of restraints, and use of as-needed medication did not change on any shift. Three patients received two or fewer doses of prescribed-as-needed medication during the 3 weeks of the study; the remaining seven patients received from 7 to 15 doses of such medication. In eight patients, weekly total use of prescribed-as-needed medication for each individual did not vary by more than two doses for any shift. In one patient (patient 5), use of prescribed-as-needed medication during the daytime shift increased from one dose at baseline to five doses during the treatment week; this patient's daytime agitation score increased from 8 to 11, and his mean daytime activity counts did not change (7,298 versus 7,534), suggesting that the increased use of prescribed-as-needed medication was not associated with clinical improvement or a

decrease in activity. In patient 6, six doses of prescribed-as-needed medication were used during the evening shift during the baseline and treatment weeks, but none were used during week 3. This patient had the largest improvement in sleep-wakefulness by nurse ratings during the treatment week and a further improvement in week 3, suggesting that use of prescribed-as-needed medication declined in response to the observed improvement. Overall, these data suggest that use of prescribed-as-needed medication did not have a direct effect on the rest-activity data or on the observed clinical benefits of light treatment.

When the clinical ratings for the last two days of each week were examined separately, the mean rank scores for sleep-wakefulness on the evening shift were nearly identical to those obtained by using the whole week summation. Results of ANOVA using these ratings was not statistically significant due to the much smaller number of data points. Other clinical ratings for the last 2 days of each week also did not change significantly.

A composite baseline score for the severity of sundowning was calculated by subtracting the summed week 1 daytime shift scores on all four clinical measures from the summed week 1 evening shift scores. One patient had a neutral sundowning score (i.e., equal to 0); the scores of the other patients ranged from 3 to 20, indicating that behaviors were in fact worse in the evening (mean sundowning score=10.9, $SD=7.0$). The severity of sundowning at baseline correlated with lower relative amplitudes of the rest-activity circadian cycle calculated from the ac-

tivity monitor data ($r=0.74$, $df=8$, $p=0.02$). Sundowning scores calculated similarly for week 2 (mean=9.2, $SD=8.0$) and week 3 (mean=3.4, $SD=3.7$) revealed a significant decrease for the posttreatment week ($\chi^2=6.2$, $df=2$, $p<0.05$, Friedman ANOVA).

A composite improvement score was calculated by subtracting the summed evening shift ratings on all clinical measures during week 2 from those of week 1. A persistence-of-effect measure was calculated by a similar subtraction of week 3 scores from week 1 scores. There was a positive correlation between the severity of sundowning at baseline and the degree of improvement with light treatment during the treatment week ($r=0.65$, $df=8$, $p=0.02$) and during the posttreatment week ($r=0.77$, $df=8$, $p=0.004$) (figure 1).

DISCUSSION

Evening bright light pulses administered for a week to patients with Alzheimer's disease who had sundowning behavior and sleep-wake cycle disturbances were associated with nurse ratings of improved sleep-wake behavior during the evening and with a decline in a measure of the severity of sundowning during the posttreatment week. Sleep-wake patterns (intradaily variability) also improved, and nighttime activity decreased, according to activity monitor measurements. These results suggest that bright light treatment may ameliorate sleep-wake cycle disturbances in some patients with Alzheimer's disease. Two reports from a group in Japan (14, 15) also suggest that phototherapy may be effective in patients with dementia, although patients with multi-infarct dementia were more likely to respond than those with Alzheimer's disease, and morning light was more effective than evening light.

This pilot study used an open-treatment, uncontrolled design. Nurses were aware of the treatment and its postulated effect, which could have influenced ratings. However, improvements in sleep-wake measures in week 2 persisted into week 3, and the sundowning score declined only in week 3, suggesting that nurse ratings were not influenced by the presence of the light treatment itself. In addition, the nurses' clinical ratings were partially corroborated by the data from the activity monitor. Nevertheless, the results of this study indicate a need for further study of bright light treatment in Alzheimer's disease using blinded raters and a no-treatment (or sham-treatment) control group.

Corresponding improvements were found according to clinical ratings and activity monitor data during week 2, but although clinical ratings suggested persistence of improvement into the posttreatment week, the activity monitor measures generally returned to baseline during the posttreatment week. It may be that these two methods of assessment are sensitive to somewhat different effects. Further studies should use both methods, perhaps with more specific, detailed, and frequent clinical ratings to help define the relationship between clinical behaviors and the circadian cycle of rest-activ-

FIGURE 1. Relation Between Severity of Sundowning and Response to Light Treatment in 10 Patients With Alzheimer's Disease

ity. Longer-term studies will be needed to determine whether beneficial effects persist over time, to document the time course of a return to baseline after treatment discontinuation, and to correlate these results with chronobiological changes. Such studies may shed light on the mechanism of action of phototherapy on sleep and behavior.

Future studies also should monitor activity for longer than 48 hours. In this study, cosinor fits were statistically significant for each of the patients during all study weeks, justifying the use of such an analysis for estimating the relative amplitude of the circadian locomotor cycle. However, the rest-activity cycle normally has a labile period (cycle duration), with cycle-to-cycle deviations that may be influenced by the environment and by conscious decisions (21). In addition, patients with Alzheimer's disease may have more day-to-day variability in their locomotor activity cycles than elderly patients without Alzheimer's disease (5, 20). On one measure of this day-to-day variability—interdaily stability—patients with Alzheimer's disease in this study had a mean value of 0.68. This finding is comparable to the 0.64 found in a previous study with similar patients, experimental conditions, and equipment (5) and is lower than the 0.81 found for age-matched control subjects in that study. In the current study, therefore, more cycles would have been required for analysis to determine true changes in locomotor period or phase, and no firm conclusions regarding these measures of the circadian locomotor cycle may be drawn from the data.

More severe sundowning at baseline predicted greater improvement on a composite of the clinical ratings. Sundowning also was associated with reduced amplitude of the circadian rest-activity cycle, and amplitude increased with light treatment. The amplitude of a circadian rhythm is thought to be the most direct reflection of the stability of that rhythm (22). Thus, these findings suggest that sundowning may be associated with disturbed circadian rhythms and that the severity of these disturbances may predict response to bright light.

Evening light pulses were used in this study because the behaviors we hoped to affect are most prominent later in the day. Studies of the phase-response curves for the effect of light pulses on circadian rhythms find phase-delays when light is given at the end of the subjective day and early in the subjective night (23). It is possible that evening light in this study exerted its effect by phase-delaying the circadian core body temperature cycle, restoring a more normal phase relationship between this cycle and a phase-delayed rest-activity rhythm. This hypothesis of a chronobiological mechanism is supported by the finding from another study that bright light pulses timed to produce an average phase-delay in core body temperature of about 2 hours were associated with significant improvements in sleep maintenance in older subjects (13). A postulated chronobiological mechanism for the effect of light on sleep would predict that treatment effects should lag behind light exposure, since steady-state phase shifts require many transient cycles to develop (23). Thus, such a mechanism is not supported by our failure to find more robust effects when the clinical data from the last 2 days of week 2 were examined separately but is supported by the persistence of treatment effects into the posttreatment week of the study. Another possible chronobiological explanation is that the beneficial behavioral effect is mediated through an increased amplitude of the endogenous circadian pacemaker, such as was observed for the locomotor activity rhythm.

Further studies should test the chronobiological hypotheses generated by this study by measuring the effect of bright light on temperature and other rhythms in behaviorally disturbed patients with Alzheimer's disease. Different baseline circadian rhythms may suggest the use of bright light pulses at other times of the day in some patients, possibly with greater effects when treatment is individualized in such a manner. Nevertheless, individual differences in response, or lack of response in some subjects, still may result from differences in sensitivity to light among patients with Alzheimer's disease, as suggested by the finding of axonal degeneration in the optic nerves of such patients (24).

Hypothalamic-Pituitary-Adrenal Axis Hyperactivity and Psychosis: Recovery During an 8-Year Follow-Up

William Coryell, M.D., and Debby Tsuang, M.D.

***Objective:** An earlier study showed that the results of the dexamethasone suppression test (DST) predicted outcome among patients with a functional psychosis followed to 1 year. The present study was undertaken to replicate these findings with a different patient group and a longer follow-up. **Method:** Ninety-two inpatients with nonorganic, nonmanic psychoses had DSTs during their hospitalizations. Raters who were blind to DST results, and to baseline chart or research diagnoses, conducted personal interviews with 71 of the patients 8 years later. **Results:** Patients who had been nonsuppressors on the DST were five times more likely than those who had been suppressors to be free of psychotic features and to exhibit insight at the follow-up interview (42% versus 8%). Prognostic differences between these groups were clear within the first year of follow-up. Baseline diagnoses also strongly predicted outcome, even among DST nonsuppressors, and DST results had no prognostic significance among patients with a baseline diagnosis of schizophrenia. Later ages at onset and short episode durations at intake also predicted recovery, but baseline DST suppressor status remained important after control for these factors. **Conclusions:** The findings of this study and those of the earlier follow-up suggest that among patients with a functional psychosis, nonsuppression on the DST is prognostically important, particularly after the exclusion of those who meet narrow criteria for schizophrenia.*

(Am J Psychiatry 1992; 149:1033-1039)

Three lines of evidence converge to suggest that hypothalamic-pituitary-adrenal (HPA) axis abnormalities have prognostic relevance to the functional psychoses. The first arises from the traditional view, supported by both short-term (1) and long-term (2) follow-up studies, that psychotic affective disorder has a much more favorable prognosis than does schizophrenia. The second consists of outcome and family studies which indicate that the diagnoses of schizoaffective disorder, schizophreniform disorder, and affective disorder with mood-incongruent psychotic features designate relatively heterogeneous groups composed both of patients with schizophrenia and of patients with affective disorder (3). The third line of evidence suggests that nonsuppression on the dexamethasone suppression test (DST) is common among patients with severe, endogenous, primary, or psychotic major depression but rare among patients with schizophrenia (4-8). Together, these trends indicate that among patients with a non-

manic, functional psychosis, those with nonsuppression on the DST will have better outcomes than those with normal DST results. Furthermore, this prediction should be more robust with greater diagnostic heterogeneity, i.e., among patients with schizoaffective disorder or major depressive disorder with mood-incongruent psychotic features.

This third assumption is much less secure than the first two; diagnostic specificity was much lower in other studies (9-12), but disparities between those two sets of studies have not been reconciled, nor are there obvious reasons for falsely high diagnostic specificity. In fact, a meta-analysis of 26 relevant studies (8) showed that overall, 19% of patients with schizophrenia but 67% of patients with psychotic major depression were DST nonsuppressors and that dexamethasone dose, timing of postdexamethasone cortisol sampling, and the presence of ongoing treatment did not account for the substantial differences in nonsuppression rates seen across studies. In addition, while the rate of nonsuppression among schizophrenic patients was much lower than that among patients with psychotic depression, it was significantly higher than that seen among normal control subjects (7%). The misclassification of psychotic major depression as schizophrenia undoubtedly accounts for some DST nonsuppression among schizo-

phrenic patients and for some of the inconsistencies across studies, but only very high rates of misdiagnosis would explain differences of this magnitude. Instead, certain subtypes of schizophrenia, such as those with predominantly negative symptoms (13, 14), may predispose patients to DST nonsuppression, and this nonsuppression may reflect physiological processes different from those producing nonsuppression among patients with psychotic major depression. There is no consensus on the existence or the nature of this subgroup, however (15, 16).

Despite the occurrence of DST nonsuppression among patients with "true" schizophrenia, the much higher likelihood of nonsuppression among patients with psychotic depression may nevertheless render the test prognostically useful in diagnostically mixed groups. This is provided, of course, that the prognosis for schizophrenia is much worse than that for affective disorder, and a number of follow-up studies suggest that this is so (2, 17). Thus, if the likelihoods of nonsuppression are 17% and 67% for patients with schizophrenia and patients with psychotic affective disorder, respectively (8), if the prognosis of affective disorder is generally good and that of schizophrenia is generally bad, and if as many as one-third of patients who exhibit both psychotic and depressive symptoms prove, in time, to have outcomes that suggest schizophrenia (18), then, among patients who show such mixed features, nonsuppressors on the DST should be approximately twice as likely as suppressors to have good outcomes.

Only a few researchers have tested such predictions. Targum (19) studied 21 schizophreniform patients for 6 months and found a modest but nonsignificant association between baseline nonsuppression on the DST and recovery. However, Maj et al. (20) detected no globally rated difference between 13 initial suppressors and nonsuppressors after 3 years. Tandon et al. (21) studied 33 patients with *DSM-III-R* schizophrenia to 1 year and noted better outcomes for nonsuppressors at 4 weeks but not at 1 year. Finally, Coryell and Zimmerman (22) studied a diagnostically mixed group of psychotic patients for 1 year and found a robust relationship between baseline DST nonsuppression and outcome. Among psychotic patients who did not meet criteria for schizophrenia, those who were definite nonsuppressors at baseline were 2.7 times more likely than DST suppressors to be free of delusions and insightful 1 year later.

The reasoning described earlier, as well as the practical implications of our earlier findings (22), led us to attempt a replication with a different patient group studied over a longer period. In doing so we wished, first, to determine whether DST results had practical and reproducible prognostic significance among patients with functional psychoses. Second, we wish to further explore the meaning of HPA axis disorder among these patients. If the DST owes its predictive qualities purely to its diagnostic specificity, then diagnosis should have little prognostic significance among nonsuppressors because nonsuppression should, in all

or nearly all cases, indicate true affective disorder. In fact, our earlier study (22) did not support this conclusion: diagnosis was as important among nonsuppressors as it was among suppressors. If nonsuppression predicts better outcomes for reasons other than, or in addition to, its diagnostic specificity, then suppressor status should be similarly predictive within each diagnostic group. Previous findings were more consistent with this pattern, although sample sizes limited conclusions (22). Finally, if the situation is more complex, nonsuppression may occur for one set of reasons among patients with schizophrenia and for other reasons in other patients. Nonsuppression might occur with substantial frequency, but have little prognostic significance, among patients with narrowly defined schizophrenia. Nonsuppression was present in eight of 31 schizophrenic patients described earlier (22), and only a trend indicated prognostic importance. In summary, patterns apparent in our earlier study tended to support the second interpretation described earlier, but conclusions were tentative pending replication.

METHOD

Subject recruitment for the previously described series (1, 22) began in June 1982 and ended in June 1985. The recruitment of a large series described by Schlessner et al. (5) ended in 1979. The intervening period was marked by clinical enthusiasm for the DST, and it was often ordered by treating physicians at our facility. The patients described in this paper, therefore, represent a study group of convenience, and the timing of these other studies determined the length of the follow-up.

We screened inpatient records at a university psychiatric hospital to find those with the following characteristics: a discharge date between December 1979 and December 1982, inclusive; a discharge diagnosis of schizophrenia, schizoaffective disorder, or major depression with psychotic features; no differential diagnosis of an organic mental disorder or mental retardation; documentation of delusions or hallucinations during the episode leading to the index hospitalization; a record of postdexamethasone cortisol values obtained at 8:00 a.m. and/or 4:00 p.m. after 1 mg of dexamethasone given at 11:00 p.m.; and the absence of any medical or pharmacological factors confounding interpretation of the DST (23). This yielded a potential subject pool of 92. Because *DSM-III* criteria for major depression specified the absence of previous mania or hypomania, and because we screened only charts with this diagnosis, this is a unipolar patient group. However, chart review revealed that one of the patients had had a probable history of mania, and this subject was retained.

Raters experienced in the structured interview of psychotic inpatients attempted to locate these individuals for follow-up. Seven (7.6%) had died and another seven could not be located. Of the remaining 78, five (6.4%) refused and two (2.6%) were not interviewable. Thus,

71 (83.5%) of those not known to be dead were successfully followed up. Sixty-four (90.1%) of the interviews were conducted in person, and four (5.6%) were conducted by telephone. Available medical records and interviews with informants provided sufficient information to assess outcome in the remaining three (4.2%) patients. Those who were interviewed on follow-up did not differ significantly from the other patients by sex or postdexamethasone cortisol values. Those lost to follow-up (including those who had died) were significantly older, however (46.2 years, $SD=19.1$, versus 33.9 years, $SD=12.5$; $t=2.8$, $df=25.3$, $p=0.01$).

Follow-up raters were blind to baseline diagnosis and DST results but were aware of the baseline psychotic features. These symptoms were tracked longitudinally to determine whether and when recovery from psychosis had occurred. Questions then focused on the preceding 3 years to determine the nature and persistence of both psychotic and depressive symptoms, the presence or absence of substance abuse, and any history of suicide attempts. The preceding year was reviewed to determine the optimum Global Assessment Scale (GAS) score (24) and to apply outcome scales proposed by Strauss and Carpenter (25). Attention was finally directed to the preceding month to further characterize ongoing affective or psychotic symptoms, to record any psychotropic drugs currently used, and to rate the overall level of psychosocial adjustment as described in the Longitudinal Interval Follow-Up Evaluation (26). In addition, raters obtained medical records pertaining to psychiatric admissions and outpatient psychiatric contacts. Their final judgments as to course and outcome reflected a synthesis of interview and medical record information.

Strauss and Carpenter (25) used five-point scales to rate outcome in four different realms: duration of non-hospitalization for psychiatric disorder, social contacts, usefully employed (including work as housewife or student), and absence of symptoms. A score of 0 corresponded to the worst outcome in each of these areas. Such a score indicated, respectively, that the subject had been hospitalized more than 9 months in the preceding year, did not meet with friends at all under any conditions, had no useful work, or had had continuous and severe signs and symptoms. A score of 4 indicated, respectively, no hospitalization in the preceding year, meetings with friends on the average of at least once a week, employed continuously, or no signs or symptoms.

The Longitudinal Interval Follow-Up Evaluation (26) global rating of psychosocial adjustment used a five-point scale to qualify functioning; a score of 1 indicated a good level of overall adjustment, while a score of 5 indicated poor adjustment or severe impairment. Recovery from affective disorder also reflected Longitudinal Interval Follow-Up Evaluation conventions and required at least 2 continuous months with no more than one or two symptoms to no more than a mild degree. Recovery from psychosis required a minimum of 2 months without delusions or hallucinations and with full insight into preexisting psychotic features.

FIGURE 1. Log-Transformed Maximum Post-DST Cortisol Values of 71 Psychotic Patients

One of us (D.T.), blind to follow-up results, reviewed all available medical records applicable to the hospitalization during which the index DST was obtained or to any earlier hospitalization. This rater noted the extent and nature of all affective and psychotic symptoms and applied diagnostic criteria according to Research Diagnostic Criteria, *DSM-III*, and *DSM-III-R*. To facilitate comparisons to the earlier study (22), this analysis used three major diagnostic groupings according to *DSM-III* criteria. The first contained all patients with major depression and mood-congruent psychotic features, and the second was a nosologically intermediate group consisting of all patients with major depression and mood-incongruent psychotic features, schizophreniform disorder, or schizoaffective disorder. The third was composed of all patients with schizophrenia.

When the results of more than one DST were available, only the first was used. These were performed within 4 days of admission for 39 patients and later in the hospitalizations for the other 32 patients. An 8:00 a.m. sample was available for 68 of the patients and a 4:00 p.m. sample for 64; for 61 patients, both 8:00 a.m. and 4:00 p.m. samples were obtained.

RESULTS

The mean and median lapses between admission and the index DST were 7.9 ($SD=9.2$) and 4 days, respectively. The mean postdexamethasone value for samples drawn within 4 days of admission was not significantly higher than that for samples obtained later, and the two groups had similar nonsuppression rates ($N=18$ of 39, or 46.2%, and 14 of 32, or 43.8%, respectively).

The index postdexamethasone cortisol values assumed a clearly bimodal distribution with a point of rarity clearly within the range of values usually used to separate normal from abnormal DST results (figure 1). In the previous study (22), a larger proportion of patients fell in the ambiguous range between 4 µg/dl and 6 µg/dl, and those patients made up a separate group in the data analysis. Because only four patients in the pres-

TABLE 1. Age and Length of Illness of 67 Psychotic Patients by Baseline DST Result^a

Item	Suppressors (N=36)		Nonsuppressors (N=31)	
	Mean	SD	Mean	SD
Age at index hospitalization (years) ^b	30.6	10.6	38.2	13.8

ent study had cortisol values in this range, they were omitted from categorical comparisons of suppressors (maximum postdexamethasone cortisol less than 4 µg/dl, N=36) and nonsuppressors (maximum postdexamethasone cortisol greater than 6 µg/dl, N=31).

Nonsuppressors had had significantly shorter episode durations than suppressors and were significantly older at intake and at the onset of illness (table 1). The majority in both groups were women (N=21, or 58.3% of suppressors and 19, or 61.3% of nonsuppressors). Nonsuppression occurred in 12 (70.6%) of the 17 patients with major depression and mood-congruent psychotic features, seven (50.0%) of the 14 patients with major depression and mood-incongruent psychotic features, four (36.4%) of the 11 patients with *DSM-III* schizoaffective disorder, three (60.0%) of the five patients with schizophreniform disorder, and five (25.0%) of the 20 patients with schizophrenia.

Three (8.3%) of the 36 patients who had been suppressors and 13 (41.9%) of 31 who had been nonsuppressors eventually recovered with insight ($\chi^2=10.3$, $df=1$, $p=0.001$). Life-table analyses showed that this difference developed early during follow-up (figure 2).

^f $t=2.7$, $df=65$, $p=0.009$.

Outcomes as reflected in GAS scores and in ratings of time in the hospital, employment, number of symptoms, and overall psychosocial adjustment also significantly favored those who had been nonsuppressors (table 2). As anticipated (3), patients with major depression and mood-congruent psychotic features were much more likely to recover than were patients with schizophrenia. Patients with major depression and mood-incongruent psychotic features, schizophreniform disorder, or schizoaffective disorder held intermediate positions (table 3).

DST results had the greatest prognostic importance within the latter group. Among these patients, suppressors and nonsuppressors differed significantly by mean GAS scores (47.9, SD=11.4, and 57.9, SD=12.4, respectively; $t=-2.3$, $df=28$, $p=0.03$). GAS scores did not differ significantly by suppressor status among patients with major depression and mood-congruent psychotic features (52.2, SD=15.5, and 56.3, SD=21.3, respectively) or among patients with schizophrenia (42.7, SD=9.2, and 40.8, SD=3.6, respectively). Among patients with major depression and mood-incongruent psychotic features, none of the seven suppressors, but four of the seven nonsuppressors, were recovered at follow-up ($p=0.03$, Fisher's exact test). On the other hand, none of the patients with *DSM-III* schizoaffective disorder had recovered although four had been nonsuppressors. Of the four schizophreniform patients, one of the two suppressors recovered, as did one of the two nonsuppressors.

Predicted relationships between duration and outcome also emerged. Baseline DST results were related to outcome when episode durations were 1 year or less;

Baseline Diagnosis	Total N	Suppressors			Nonsuppressors		
		N	Recovered ^b		N	Recovered ^c	
			N	%		N	%
Major depression with mood-congruent psychotic features (A)	17	5	2	40.0	12	8	66.7
Major depression with mood-incongruent psychotic features or schizophreniform or schizoaffective disorder (B) ^d	30	16	1	6.3	14	5	35.7
Schizophrenia (C)	20	15	0	0.0	5	0	0.0

^aData not included for four patients with post-DST cortisol values of 4–6 µg/dl.

^bA versus B versus C: $p=0.04$ (Fisher's exact test); A>C: $p=0.05$ (Fisher's exact test).

^cA versus B versus C: $p=0.03$ (Fisher's exact test); A>C: $p=0.02$ (Fisher's exact test).

^dSuppressors versus nonsuppressors: $p=0.05$ (Fisher's exact test).

three of the 26 suppressors (11.5%) and 13 of the 28 nonsuppressors (46.4%) with these durations recovered ($\chi^2=7.9$, $df=1$, $p<0.005$). None of the patients with longer episode durations recovered, even though three had been nonsuppressors.

Also as expected, a later age at onset was associated with a higher likelihood of recovery; the mean age at onset was 25.2 years ($SD=8.5$) for those who did not recover and 32.2 years ($SD=13.0$) for those who did (Wilcoxon rank sum test, $z=2.06$, $p=0.04$). Current age was not a significant predictor of recovery.

Because age at onset, episode duration, and diagnosis were each associated both with the likelihood of recovery and with postdexamethasone cortisol values, they were entered into a logistic regression analysis with recovery as the dependent variable (table 4). With episode duration, diagnosis, and age at onset in the model, suppressor status remained a significant predictor of outcome. The significant relationship between suppressor status and outcome also persisted in a logistic regression analysis from which the 20 schizophrenic patients were excluded. Age at onset was not a significant predictor among nonschizophrenic patients and was therefore not included in this model.

One of the four patients with postdexamethasone cortisol values in the ambiguous range (4–6 mg/dl, inclusive) was recovered from psychosis at follow-up. Six (46.2%) of the 13 patients with values greater than 6 µg/dl but less than 10 µg/dl were recovered, while seven (38.9%) of the 18 with values greater than 10 µg/dl recovered. These data did not suggest an optimal threshold for predicting recovery other than the conventional one approximating 5 µg/dl.

DISCUSSION

DST results among the psychotic inpatients were strongly associated with outcome on follow-up. In this regard, these data clearly confirm our earlier findings (22) and increase the likelihood that this relationship is generalizable. The two studies also concur in finding an interdependence between DST results and diagnosis in the prediction of outcome; nonsuppressors who had major depression had much better outcomes than did nonsuppressors who had schizophrenia. Thus, the prog-

TABLE 4. Logistic Regression Analysis of Baseline Measures and Recovery of Psychotic Patients After 8 Years

Model and Variable	Likelihood Ratio Test, χ^2 ($df=1$)	p

^a $\chi^2=30.4$, $df=4$, $p<0.0001$, $R=0.55$, $N=67$.

^b $\chi^2=19.1$, $df=3$, $p=0.0003$, $R=0.47$, $N=47$ (schizophrenic patients excluded).

nostically favorable significance of DST nonsuppression cannot be attributed solely to its diagnostic specificity. The situation is apparently more complex.

In both studies DST nonsuppression occurred among patients with a diagnosis of schizophrenia, but in neither was suppressor status significantly associated with outcome among schizophrenic patients. What, if anything, does DST nonsuppression signify in schizophrenia? While some researchers have failed to find clinical differences between schizophrenic patients who are DST suppressors and schizophrenic patients who are DST nonsuppressors, those who have consistently noted that nonsuppressors were more likely to have disorganized (27) or type II (13, 14) schizophrenia or were less likely to have positive symptoms (9). In the present study as well, patients with disorganized or hebephrenic schizophrenia were more likely to be nonsuppressors than were other schizophrenic patients (two of five, or 40%, versus two of 13, or 15.4%). Disorganized or type II forms of schizophrenia, in turn, have been associated with higher ventricle-brain ratios (28) and with cognitive deficits (29, 30) which may be quite severe (31). The fact that patients with dementia also have substantial rates of DST nonsuppression (32) invites speculation that a process common to chronic, type II schizophrenia and to irreversible dementia may give rise to DST nonsuppression in these conditions.

The correlates of DST nonsuppression in the affective disorders indicate a different underlying mechanism. Nonsuppression among depressed patients has been most consistently associated with severity, as reflected in endogenous, psychotic, or seriously suicidal features (33). Moreover, the clinical phenomena characteristic of patients with affective syndromes and atypical psychotic features (schizoaffective disorder or major depression with mood-incongruent psychotic features) suggest that it is type I and not type II schizophrenia that is liable to inclusion in these groups. In two large series, patients with Research Diagnostic Criteria (34) schizoaffective depression rarely exhibited blunted or inappropriate affect or formal thought disorder (18, 35). If, as these data suggest, type II schizophrenic patients are seldom misdiagnosed as having affective or schizoaffective disorders, they will be found only among patients who meet strict criteria for schizophrenia. Therefore, DST nonsuppression may be highly specific to true affective disorder among psychotic patients only after those who meet narrow definitions of schizophrenia have been excluded.

Notably, however, the distinctions between major depression with mood-congruent psychotic features on the one hand, and schizoaffective disorder or major depression with mood-incongruent psychotic features on the other, were prognostically important among DST nonsuppressors as well as among DST suppressors. While some cell sizes were quite small, the overall patterns here closely resembled those of our earlier study (22). This suggests that there are two reasons for the relatively poor prognoses regularly seen among depressed patients with mood-incongruent psychotic features (36). Some of these patients may not have affective disorder but may instead have schizophrenia; this view is supported by much repeated family history findings (3). Among those who do not have schizophrenia, however, mood-incongruent psychotic features may indicate a relatively persistent and disabling form of true affective disorder.

While we expected the differences we found in recovery rates by diagnosis and DST status, we did not expect overall rates to be as low as they were. Our earlier study (22) recruited patients from the same facility and employed the same diagnostic criteria and the same definition of recovery on follow-up. Yet that study found that recovery had occurred after only 1 year in 17 (70.8%) of 24 patients with major depression with mood-congruent psychotic features, 14 (45.2%) of 31 patients with major depression with mood-incongruent psychotic features, and four (12.9%) of 31 patients with schizophrenia. Corresponding figures in the present study were 10 (58.8%) of 17, six (20.0%) of 30, and none of 20, respectively. Thus, recovery rates were lower in each diagnostic group despite a much lengthier follow-up period. We cannot account for these differences across studies. However, the fact that the same outcome predictors emerged in both studies (episode duration, *DSM-III* diagnosis, and DST result) indicates that outcome ratings were reliable and valid.

Both the present results and those of the first series (22) support the following approach to prognosis in patients with nonmanic psychosis. A narrowly defined diagnosis of schizophrenia implies a low likelihood of full recovery; DST results may be prognostically meaningless for these patients, or nonsuppression may even portend a worse prognosis. Patients who have *DSM-III* diagnoses of major depression with mood-congruent psychotic features, major depression with mood-incongruent psychotic features, or schizoaffective disorder have, as a group, better outcomes than those who meet criteria for schizophrenia. Among these patients, however, those with abnormal DST results (nonsuppressors) have significantly better outcomes than those with normal DST results.

The Dexamethasone Suppression Test in Adolescent Outpatients With Major Depressive Disorder

Harris Rabinovich, M.D., Paul Ambrosini, M.D., Mayadah Al-Shabbout, M.A.,
Hana Novacenko, M.S., Beverly Nelson, R.N., and Joaquim Puig-Antich, M.D.

Objective: The purpose of the study was to determine whether the dexamethasone suppression test (DST) would discriminate between outpatient adolescents with major depressive disorder and normal adolescent comparison subjects. **Method:** Depressed patients were accepted into the study only if they fulfilled the Research Diagnostic Criteria for major depressive disorder. The depressed subjects (N=44) and the normal subjects (N=38) were studied in the same environment and under the same conditions. The subjects received 1 mg of dexamethasone at 11:00 p.m. The next day, blood for determining plasma cortisol concentrations was drawn through an indwelling catheter every 60 minutes from 8:00 a.m. until 11 p.m. **Results:** After dexamethasone, the cortisol levels of the adolescents with major depressive disorder and the normal subjects were not significantly different. Only six (14%) of the depressed subjects and one (3%) of the normal subjects showed evidence of nonsuppression (cortisol value greater than 5 µg/dl). Analyses of subgroups of the depressed patients based on suicidal tendencies and endogenous subtype also failed to reveal significant differences in cortisol values. Estimates of the severity of depression showed significant negative correlations with cortisol values among the depressed patients. **Conclusions:** In contrast with previous studies of adolescent inpatients, the DST did not discriminate between the adolescent outpatients with major depressive disorder and the normal comparison subjects in this study. Possible reasons for the discrepancies, such as severity of the depression and inpatient status, are discussed.

(Am J Psychiatry 1992; 149:1040-1045)

There has been controversy concerning the role of the dexamethasone suppression test (DST) as a tool for the diagnosis of major depressive disorder in adults, children, and adolescents. Casat et al. (1) reviewed the available studies on the use of the DST in children and adolescents. There were eight studies on adolescents (2-9), with a total of 475 inpatients, of whom 157 (33%) had major depressive disorder. These studies used a prospective design, the Research Diagnostic Criteria, or *DSM-III* criteria for diagnosis and included one or more control groups. In all of them, 1 mg of dexamethasone was administered at 11:00 p.m. In most of the studies, blood samples for determination of cortisol levels were drawn at 4:00 p.m. and 11:00 p.m.

on the day after dexamethasone administration. Casat et al. showed that 74 (47%) of the adolescent inpatient subjects with major depressive disorder and 63 (20%) of the subjects with other psychiatric disorders were nonsuppressors of cortisol ($\chi^2=3.84$, $df=1$, $p<0.0001$). When a serum cortisol level of 138 nmol/liter (5 µg/dl) was used as the threshold for nonsuppression, the pooled DST sensitivity and specificity were 47% and 80%, respectively.

Our study adds uniquely to the existing literature on the DST in adolescent major depressive disorder by virtue of the following four main features. 1) It used a large *outpatient* group of depressed adolescents. 2) Both depressed and normal subjects were studied in the same environment and under the same conditions. 3) After administration of dexamethasone, cortisol levels were determined each hour from 8:00 a.m. to 11:00 p.m. (i.e., 16 times) from blood drawn through an indwelling venous catheter. 4) The majority of these adolescent subjects had also participated in another study of 24-hour baseline cortisol measures, permitting within-subject comparisons of 24-hour baseline cortisol levels with DST cortisol levels.

METHOD

Patients were accepted for screening at a child and adolescent depression clinic if they were reported to appear sad, said they felt sad, had suicidal ideation or behavior, were nervous or afraid, or displayed ritualistic behavior. After informed consent was obtained, each patient was screened for appropriateness for the study in a 10- to 14-day diagnostic evaluation that included, in the following order, the Schedule for Affective Disorders and Schizophrenia for School-Age Children, Present Episode (KIDDIE-SADS-P) (10), the Psychosocial Schedule (11), a pediatric history and examination including Tanner staging (12, 13), and, 10–14 days later, another KIDDIE-SADS-P covering the past week. The second KIDDIE-SADS-P assessment was done without knowledge of the findings of the first. The diagnosis of major depressive disorder was made with the unmodified adult Research Diagnostic Criteria (RDC) (14). The diagnoses of nonaffective emotional disorders conformed to *DSM-III* criteria.

All subjects were between the ages of 11 and 18 years and had reached at least Tanner stage III of sexual development, as determined by a pediatrician. Depressed subjects were accepted into the study only if they fulfilled the RDC for major depressive disorder (at least probable) in both KIDDIE-SADS-P evaluations. Major depressive disorder was considered to be endogenous only if it fulfilled the RDC for definite endogenous subtype in both evaluations. If not, subjects were classified as having the nonendogenous subtype.

Potential subjects were excluded if they met any of the following criteria: 1) use of psychoactive medication that could affect hypothalamic-pituitary function, 2) significant physical illness, especially endocrinopathies or heart disease, 3) obesity (weight-for-height greater than 95% on the National Center for Health Statistics curve) or growth failure (height or weight lower than the third percentile), 4) clinically diagnosed seizures or other major neurological illness, 5) IQ less than 70, 6) fulfillment of the *DSM-III* criteria for anorexia nervosa, autism, or schizophrenia, and 8) inordinate fear of needles (needle phobia).

Normal comparison subjects were recruited through personal contacts and informal networking. The exclusion criteria enumerated above were also used for this group. The criterion for inclusion was no current or past history of child psychiatric disorder, as determined by a single KIDDIE-SADS-E assessment (mother and child interviewed independently).

Eighty-two subjects were accepted for the study: 44 patients with major depressive disorder (24 had the endogenous subtype, 19 were suicidal, and four were psychotic) and 38 normal comparison subjects. Two of the subjects had more than two missing data points at the end of the testing and were dropped from the study. There were no significant group differences in age (patients with major depressive disorder: mean=14.9 years, SD=1.9; normal subjects: mean=15.3 years, SD=1.5), sex (patients: 22 female and 22 male; normal sub-

jects: 13 female and 25 male), or race (patients: 28 white, six black, and 10 other; normal subjects: 21 white, eight black, and nine other).

Severity of depression was assessed by examining scores on the KIDDIE-SADS-P and by extracting scores on the 21-item Hamilton Rating Scale for Depression from the KIDDIE-SADS-P scores with an adaptation of the method of Endicott et al. (15). The mean Hamilton depression score for the patients with major depressive disorder was 24.7 (SD=4.3). There was no statistically significant difference in Hamilton depression scores between patients with endogenous major depression (mean=25.2, SD=5.0) and those with nonendogenous depression (mean=24.1, SD=3.1) ($t=0.87$, $df=39$, $n.s.$). The patients with suicidal ideation (score of 4 or more on the KIDDIE-SADS-P item for suicide, indicating a definite plan or attempt) tended to have higher Hamilton depression scores (suicidal, mean=26.1, SD=5.0; not suicidal, mean=23.7, SD=3.4) ($t=1.86$, $df=41$, $p=0.07$). There were significant differences in Hamilton depression scores between the male and female depressed patients (male, mean=23.3, SD=4.3; female, mean=26.2, SD=3.7) ($t=2.35$, $df=41$, $p=0.02$).

After the 2-week diagnostic protocol and acceptance into the study, subjects came to a sleep/neuroendocrine unit to be tested. An indwelling catheter was placed in an antecubital vein, and the vein was kept open by a slow drip of heparinized saline. Blood samples were immediately centrifuged, and the plasma was separated and then frozen.

Plasma cortisol was analyzed by competitive protein-binding radioassay with intra-assay coefficients of variation of 9.1%, 3.7%, and 2.4% at 68.9, 342.1, and 557.3 nmol/liter, respectively, and interassay coefficients of variation of 9.6%, 3.9%, and 4.8% at the same levels.

This study was part of a psychobiological study of children with major depressive disorder that included the following general neuroendocrine and sleep measures: night 1: sleep EEG; day 1: thyrotropin-releasing hormone (TRH) challenge tests; night 2: sleep EEG; day 2: 24-hour test of blood cortisol levels; night 3: sleep EEG; day 3: morning, insulin tolerance test; 3:00 p.m., amphetamine challenge test; 11:00 p.m., administration of 1 mg p.o. of dexamethasone; day 4: testing of blood cortisol levels hourly from 8:00 a.m. until 11:00 p.m. Approximately 90% of the subjects participated in the full protocol. The other 10% participated only in the amphetamine challenge test and the DST. There was no difference in DST results between the latter subjects and those who participated in the full protocol.

A subgroup of 14 subjects (eight patients with major depressive disorder and six normal subjects) participated in an earlier version of the DST protocol with the indwelling catheter, but plasma sampling was done only at 8:00 a.m., 4:00 p.m., and 11:00 p.m. The data of these subjects were included only in the analyses of those time points. Thus, for the 16-hour analysis we included data on only 66 subjects: 35 patients with major depressive disorder (19 endogenous, 16 suicidal,

three psychotic) and 31 normal comparison subjects. This subgroup of subjects (hereafter referred to as the "reduced group") participated in all of the studies we have described, and the protocol was in all other ways identical to that for the rest of the group. As in the full group of subjects, there were no significant differences in age, sex, or race between the depressed patients and the normal subjects in the reduced group.

In the statistical analysis, cortisol levels were examined for normality with the W statistic of Shapiro and Wilk (16) and transformed as necessary before testing with parametric techniques. If, after transformation, the measures were still significantly abnormal, non-parametric techniques (e.g., the Mann-Whitney test) were used for between-group comparisons. Spearman correlation coefficients were used to examine the associations between cortisol levels and severity of depression. The problem of missing data was minimal. The two subjects who had more than two consecutive missing samples were excluded from all examinations of the mean 16-hour cortisol levels. One or two missing samples from a single subject were linearly interpolated.

RESULTS

After the administration of dexamethasone, there were no significant differences between the depressed group and the normal group on the following summary variables: mean 16-hour cortisol level, peak cortisol level, and mean cortisol level measured at each of the 16 testing times, including cortisol levels for "standard" testing times (8:00 a.m., 4:00 p.m., and 11:00 p.m.) (table 1, figure 1). Repeated measures analysis of variance with the Greenhouse-Geisser adjustment (17) showed a significant effect of time ($F=4.4$, $df=4.4$, 284.4 , $p=0.002$) but not a significant Time by Diagnosis interaction ($F=1.05$, $df=4.4$, 284.4 , $p=0.40$). There was no significant difference between the depressed patients and the normal subjects in the percentage of samples with cortisol values of 138 nmol/liter (5 μ g/dl) or more. These summary cortisol variables and the percentage of

FIGURE 1. Sixteen-Hour Postdexamethasone Plasma Cortisol Levels of Adolescents With Major Depressive Disorder and Normal Adolescent Comparison Subjects

samples with cortisol values of 138 nmol/liter or more also failed to discriminate among the subgroups of patients with major depressive disorder (suicidal, endogenous, and psychotic). Contrary to our expectation that patients with more severe depression would show higher postdexamethasone plasma levels of cortisol, we found a *negative* correlation between severity of depression and mean 16-hour cortisol level ($r_s=-0.46$, $N=34$, $p=0.006$), peak cortisol level ($r_s=-0.50$, $N=34$, $p=0.003$), 4:00 p.m. cortisol level ($r_s=-0.43$, $N=43$, $p=0.004$), 11:00 p.m. cortisol level ($r_s=-0.30$, $N=43$, $p=0.06$), and mean cortisol level for blood samples taken at 8:00 a.m., 4:00 p.m., and 11:00 p.m. ($r_s=-0.40$, $N=43$, $p=0.02$).

Exploratory analyses of covariance revealed no significant effects of age, sex, or the Age by Sex and Age by Diagnosis interactions on any of the summary cortisol variables for the full study group. Within the reduced group, the female subjects had significantly higher hourly and mean 16-hour postdexamethasone cortisol levels than the male subjects (female: mean=28.1 nmol/liter, $SD=19.3$; male: mean=23.9 nmol/liter, $SD=33.5$) ($U=705$, $p<0.02$).

In addition to the continuous variable analyses, we explored categorical comparisons of our data with data from clinically based studies that used the concept of a cutoff value to indicate nonsuppression of cortisol. We chose a standard cutoff of 138 nmol/liter (5 μ g/dl) at any of the three usual time points (8:00 a.m., 4:00 p.m., and 11:00 p.m.) to define nonsuppression. This revealed that six of the 44 patients with major depressive disorder were nonsuppressors, compared to one of the 38 normal subjects ($p<0.20$, Fisher's exact test). Comparison of clinical variables (Hamilton depression scores, endogenous subtype, sex, suicidality, and age) between the nonsuppressors ($N=6$) and the rest of the group with major depressive disorder ($N=38$) revealed no significant differences.

Approximately 90% of the subjects in this research

also participated in a study of 24-hour baseline cortisol secretion. In that study, Dahl et al. (18) reported no significant differences in the peak, nadir, or time of the nocturnal rise of plasma cortisol between patients with major depressive disorder and normal subjects. We examined the relation between the mean 24-hour baseline cortisol levels from that study and the postdexamethasone mean 16-hour cortisol levels in this study and found a significant positive correlation ($r_s=0.54$, $N=64$, $p<0.0001$).

We used receiver operating characteristic analysis (19) to explore the sensitivity and specificity of the DST. This curve is a standard way of showing the various possible pairs of test sensitivity (rate of true positives) and specificity (1 minus the rate of false positives) at various cutoff scores. We analyzed the mean 16-hour, peak, 8:00 a.m., and 4:00 p.m. cortisol values for 100 cutoff scores (from 0.0 nmol/liter to 220.7 nmol/liter). All of the receiver operating characteristic curves obtained were not significantly different from the expected random receiver operating characteristic curve. (Figure 2 shows the receiver operating characteristic curve for cortisol values at 4:00 p.m.) For comparison with other studies, we also used 138 nmol/liter (5 $\mu\text{g/dl}$) as the cutoff cortisol value to define nonsuppression. With this cutoff level, the sensitivity and specificity for 8:00 a.m. and 4:00 p.m. were 9.0% and 100%, respectively. Sensitivity and specificity were identical when 4:00 p.m. values were used.

DISCUSSION

In contrast with previous *inpatient* adolescent studies, the DST in our sample of outpatients did not discriminate between patients with major depressive disorder and normal comparison subjects. Similarly, our group has also reported (20) that in a large group of prepubertal subjects with major depressive disorder (predominantly outpatients), the DST did not discriminate among subjects with major depressive disorder, those with nonaffective psychiatric disorders, and normal subjects.

The reason for these discrepancies with previous reports on inpatients is not clear. Possible factors contributing to positive findings with inpatient subjects include 1) severity of depression in the subjects being studied and 2) stress induced by the hospitalization.

In adults, high rates of DST nonsuppression are associated with greater scores on severity of depression (21). Because of this association, one must consider possible differences in severity as contributing to the negative results in this study. Our results in adolescents do not support this explanation. Our overall study group had Hamilton depression scale scores indicating moderate to high severity. Further, in contrast with the reports on the DST with adults, the correlation between severity scores and post-DST cortisol levels was *negative*. Thus, it appears unlikely that severity is the sole answer to these discrepancies, at least in the adolescent age group.

FIGURE 2. Receiver Operating Characteristic (ROC) Curve for Post-dexamethasone Plasma Cortisol Levels at 4:00 p.m. in Adolescents With Major Depressive Disorder and Normal Adolescent Comparison Subjects

We believe that a second important source of variance, potentially contributing to differences between the results of our studies and the existing literature on depressed inpatient adolescents, is the stress of hospitalization. The relatively low-stress environment in our sleep laboratory (to which the adolescents had adapted during the psychobiological protocols) may not have been sufficient to uncover a vulnerability to stress associated with depression. In previous studies, the stress of being on an inpatient unit may have contributed to the positive DST findings.

Stress such as surgery, preoperative surgery procedures, examinations, and admission to the hospital may trigger a large transient rise in cortisol production (for reviews of this subject see 22, 23). To our knowledge there are no studies of adolescents that have directly addressed this issue. The few studies of children have shown the same trends. For example, Tennes and Kreye (24) showed that grade-school subjects had significantly higher urinary cortisol levels on mornings when classroom examinations were scheduled than on other days. Knight et al. (25) demonstrated that children, particularly those who denied stress, had significantly increased urinary cortisol secretion after admission to the hospital for elective surgery. Barnes et al. (26), studying children undergoing open heart surgery, found that urinary 17-hydroxycorticosteroids were significantly elevated on the day before surgery and on the day of return from intensive care.

It is likely that stress increases the rate of nonsuppression of cortisol after administration of dexamethasone. There are no studies of stress-induced nonsuppression of cortisol on the DST in children or adolescents. In adult psychiatric and medical patients, hospitalization has been found to induce an increase in the rate of nonsuppression on the DST in the first 48 hours after admission (21). Ceulemans et al. (27) administered the DST to 40 presurgical patients and 20 normal control

subjects. They found that all of the control subjects were suppressors, but 47.5% of the presurgical patients were nonsuppressors. Blumenfeld et al. (28) found impaired urinary 17-hydroxycorticosteroid suppression after dexamethasone administration in military trainees under stress. Baumgartner and Kurten (29) showed that depressed patients, schizophrenic patients, and normal volunteers under stress (giving a lecture) had similar rates of cortisol nonsuppression (56.5%, 50.0%, and 43.8%, respectively).

The indwelling catheter itself may also cause stress; however, in this study the blood samples were drawn after subjects had adapted to the laboratory environment and the indwelling catheter. Another group of subjects in the same laboratory, who were following similar protocols, were assessed for stress. They indicated that the degree of subjective stress was quite low and that the indwelling catheter as a rule caused little discomfort (30). In previous studies, subjects experienced the combined stress of repeated venipunctures and the hospitalization process (particularly when the DST was done shortly after admission). In some studies, these combined stresses may have interacted to produce nonsuppression.

In summary, stress increases baseline cortisol levels as well as nonsuppression of cortisol on the DST. It may contribute to the differences in the results of inpatient and outpatient investigations that we have described.

In this study, we found a negative correlation between severity of depression and cortisol level. Thus, patients with high Hamilton depression scores had lower post-DST cortisol levels. This finding is the opposite of what we expected and needs further exploration.

One limitation of this study was that serum dexamethasone levels were not ascertained. Several studies of adults with major depressive disorder have reported a significant negative correlation between cortisol and dexamethasone levels (31–35), suggesting that cortisol nonsuppressors have a lower level of plasma dexamethasone than cortisol suppressors. Naylor et al. (36) studied 73 inpatient children aged 5–14 years and found that overall, DST nonsuppressors had significantly lower plasma dexamethasone levels than suppressors; similar nonsignificant trends were observed in the depressed subjects. In addition, our group (20) studied 24-hour plasma levels of dexamethasone in children with major depressive disorder and found no statistically significant difference in dexamethasone levels between the suppressor and nonsuppressor depressed patients and also no difference between the depressed patients, the patients with nonaffective psychiatric disorders, and the normal subjects.

A second potential limitation of this study was the dose of dexamethasone administered. It is possible that a lower dose might have improved the sensitivity of the DST in this group of patients. However, to our knowledge there have been no studies comparing dexamethasone dosages in adolescents. Only two studies of children have addressed this issue. Doherty et al. (37) investigated dose response and reported that there were

no significant differences in the percentages of children who were nonsuppressors in response to low, medium, and high doses of dexamethasone based on body weight. On the other hand, Naylor et al. (36) did not find a correlation between milligram-per-kilogram dexamethasone dose and plasma dexamethasone concentration, but they did find a significant correlation with body surface area.

Although our data suggest that the DST may not have clinical utility, there may be research value in delineating a biologically distinct subgroup of depressed subjects who do not suppress cortisol on the DST. Particularly with young subjects, the long-term follow-up of this biologically distinct subgroup may provide essential information. Along these lines, we have some follow-up data that concern our subjects, although they did not have systematic clinical follow-up. Rao et al. (38) recently began the process of identifying and following up a wide range of children and adolescents initially studied by the Puig-Antich et al. group, including adolescents from the present study. Rao et al. have located approximately 78% of the subjects with major depressive disorder across studies and have found that eight committed suicide. Three of those eight were subjects in this study, two of whom had shown nonsuppression of cortisol on the DST. Although this is primarily an anecdotal observation (not a statistically significant finding), it is provocative that at least two of the six nonsuppressors committed suicide. This finding is also interesting because of previous reports that suicidal ideation was correlated with high basal cortisol secretion near sleep onset in adolescents with major depressive disorder (39), high urinary free cortisol (40), and nonsuppression of cortisol on the DST (41–45). Controlled longitudinal follow-up studies in combination with the DST and other biological measures will be needed to address this relationship.

In conclusion, both baseline cortisol levels (18) and cortisol levels after dexamethasone in the adolescents we studied failed to show significant group differences, suggesting that the hypothalamic-pituitary-adrenal axis was functionally normal in the overall sample of depressed adolescents. There was a small subgroup of nonsuppressors who did not appear to be clinically distinct from the rest of the group with major depressive disorder. Clinical follow-up of this group may help to delineate the possible role of the DST as a research tool.

Relapse After Cognitive Behavior Therapy of Depression: Potential Implications for Longer Courses of Treatment

Michael E. Thase, M.D., Anne D. Simons, Ph.D.,
Janice McGeary, R.N., B.S., John F. Cahalane, M.S.W.,
Carol Hughes, M.S.W., Tim Harden, B.A., and Edward Friedman, M.D.

Objective: The authors studied the risk of relapse among depressed patients after cognitive behavior therapy in order to document the need and potential indications for longer-term models of treatment. **Method:** Forty-eight patients with major depression who responded during a 16-week course of cognitive behavior therapy entered a 1-year prospective follow-up study, as did two patients who received 20 weeks of therapy. Standardized, independent clinical assessments were completed 1, 3, 6, 9, and 12 months after treatment. Relapse was defined as, at minimum, a 2-week period in which the subject met the DSM-III-R criteria for major depression and had a Hamilton depression scale score of 15 or more. **Results:** Sixteen patients (32%) relapsed during the 1-year follow-up. Correlates of relapse included a history of depressive episodes, higher levels of depressive symptoms and dysfunctional attitudes, slower response to therapy, and being unmarried. Patients who fully recovered during therapy (Hamilton depression score of 6 or less for 8 weeks or more) were at significantly lower risk for relapse than those who partially recovered (9% and 52%, respectively). Slower response to therapy, unmarried status, and high residual scores on the Dysfunctional Attitudes Scale were independently and additively related to increased risk of relapse. **Conclusions:** These findings provide further evidence of a relation between residual symptoms and relapse after cessation of active treatment. The authors strongly recommend that models of longer-term psychotherapy be developed for depressed patients who do not recover fully during time-limited cognitive behavior therapy.

(Am J Psychiatry 1992; 149:1046-1052)

A number of studies over the past 15 years have indicated that cognitive behavior therapy (1) is an effective short-term outpatient treatment of depression (2). Indeed, there is some suggestion that an initial, time-limited course of cognitive behavior therapy may convey additional prophylactic benefits after termination of therapy (3-7). Nevertheless, relapse after termination of acute treatment of depression remains a significant public health problem (8, 9), and, more specifically, the maintenance of therapeutic gains after short-term cognitive behavior therapy is far from complete (3-7). We therefore initiated a prospective, longi-

tudinal study of patients who had been treated with cognitive behavior therapy in the Psychobiology of Recovery in Depression project (10, 11). One goal of the longitudinal study was to document the frequency of relapse during the first year of follow-up as a way of determining whether there is a need for developing longer-term models of cognitive behavior therapy. A second goal was to identify clinical correlates of relapse that might help clinicians to identify patients who would be likely to benefit from such continued therapy. We now report the 1-year outcome and clinical correlates of relapse in a study of 50 patients who responded during time-limited cognitive behavior therapy.

METHOD

The recruitment, screening, assessment, and treatment of outpatients participating in the Psychobiology of Recovery in Depression project protocol have been described in detail elsewhere (10, 11). To summarize briefly, patients were initially evaluated by a team of

clinician-psychiatrists, and if they met the *DSM-III-R* criteria for major depression, they were seen subsequently by our research team for a secondary evaluation, which included medical history, physical examination, laboratory screening studies (CBC, chemistry screen, and thyroid function tests), and an independent research interview using the Schedule for Affective Disorders and Schizophrenia (SADS) (12) and the 17-item Hamilton Rating Scale for Depression (13).

On the basis of these evaluations, patients were offered enrollment in the study only if they 1) met the Research Diagnostic Criteria (RDC) (14) for a diagnosis of primary major depression (nonbipolar, nonpsychotic subtype) of 18 months' duration or less; 2) met the RDC for probable or definite endogenous subtype; 3) had Hamilton depression scale scores of 15 or more; 4) did not suffer from untreated or poorly controlled conditions that may cause depression (e.g., hypothyroidism), invalidate EEG sleep studies (e.g., sleep apnea), or require treatment with agents that may do either (e.g., β blockers); 5) did not meet criteria for antecedent dysthymia (*DSM-III-R*) or minor or intermittent depressive disorders (14); 6) had no history of active drug or alcohol abuse or dependence (either primary or secondary) during the 2 years before intake into the study; 7) were not judged to have severe intercurrent personality pathology according to *DSM-III-R* criteria (for example, patients with well-established diagnoses of borderline or antisocial personality disorder at the intake interview were excluded); and 8) provided written informed consent. These inclusion and exclusion criteria were designed to yield a homogeneous study group of persons who were in an acute or subacute episode of moderate to moderately severe major depression.

Of more than 130 patients who were evaluated for eligibility, 80 met the entry criteria and 76 enrolled in the study. The two major reasons for exclusion from the protocol were insufficient severity of RDC endogenous features and chronicity of the index episode. Only one potentially eligible patient from this nearly consecutive series of patients newly accepted for therapy refused the protocol in favor of pharmacotherapy; three other potentially eligible patients were referred by the secondary assessment team for immediate (nonresearch) treatment because of marked severity of depression and suicidal tendencies.

After completion of all research assessments, cognitive behavior therapy was begun. The patients received no psychotropic medications during the entire course of treatment. Therapy was conducted according to the manual of Beck et al. (1) with a 16-week, 20-session outpatient protocol (twice-weekly sessions for 4 weeks and weekly sessions thereafter). The therapists had completed at least 2 years of supervised training and had received external certification according to the standards established for use in the National Institute of Mental Health Treatment of Depression Collaborative Research Program (15). Unlike the therapists in the collaborative study, however, the therapists received ongoing weekly supervision.

During the course of treatment, the patients were seen biweekly for independent assessments of symptomatic status according to the Hamilton depression scale, the Beck Depression Inventory (16), and the Global Assessment Scale (GAS) (17). In addition, the Dysfunctional Attitude Scale (unpublished scale by A. Weisman and A.T. Beck, reviewed by Merluzzi and Boltwood [18]) was administered at the beginning and end of the acute treatment protocol. The reliability of the diagnostic measures and clinician-rated scales had been established during a pilot phase of the study and monitored annually according to the standards of our mental health clinical research center (19). Upon completion of the treatment protocol, patients were considered nonresponders if they met the following criteria: 1) less than 50% reduction in Hamilton depression scale score since pretreatment assessment, 2) final Hamilton depression scale score higher than 10, and 3) inability to sustain response for at least 2 weeks by week 16.

Of the first 76 patients to enter the treatment protocol, two (3%) withdrew during the first week of therapy and 10 others (13%) did not complete the entire protocol. The 64 patients who did complete the protocol included 12 (19%) who met the criteria for nonresponders. Alternative treatments were available for these patients. Fifty patients (78% of the completers) had at least 2 consecutive weeks in which their Hamilton depression scale scores were 10 or lower and had 50% or greater reductions from their pretreatment Hamilton depression scores. Forty-eight of these 50 patients enrolled in the follow-up study. Two other patients met the Hamilton depression scale criteria for nonresponse at week 14 but had scores within the responder range at week 16. Both of these patients received 4 additional weeks of therapy and entered the follow-up study after meeting response criteria at week 20.

For the purposes of the follow-up study, we operationalized the definition of Keller et al. (20) for recovery from unipolar depression as follows: a stable reduction of Hamilton depression scale scores to 6 or less for at least 2 months (from weeks 8 through 16 of the treatment protocol). According to this definition, 23 (46%) of the 50 patients who entered the follow-up study were considered recovered; the remaining 27 patients (54%) were classified as partially recovered at the beginning of the follow-up period.

During the first year of follow-up, patients were seen by an independent clinical evaluator 1, 3, 6, 9, and 12 months after treatment. All patients were guaranteed a renewed course of therapy in the event of relapse. Accordingly, patients were encouraged to contact the protocol staff for additional emergency evaluations if they were concerned that their condition was deteriorating. Follow-up evaluations consisted of an update of clinical and medical status, including notation of any treatment contacts or use of medication. At each visit the patient completed the Beck Depression Inventory, and the evaluator rated the patient's clinical status with the Hamilton depression scale and the GAS. The evaluator also inquired whether the patient had experienced any wors-

ening of his or her condition during the interval since the most recent assessment (i.e., a 1- to 3-month interval) that might not be reflected by the current status. A checklist summarizing the *DSM-III-R* criteria for major depression was completed by the independent evaluator at each visit to describe the patient's syndromal status at the worst point during the follow-up interval.

Patients were considered to have relapsed if at any time they 1) met the *DSM-III-R* criteria for major depression for a minimum of 2 weeks and 2) had a Hamilton depression score of 15 or more. All relapsed patients were retreated by our program. We also recorded when patients reentered treatment for other reasons and when they met the less restrictive criteria for partial relapse (minor or intermittent depression according to the RDC), experienced a transient worsening that had lessened by the time of assessment, and/or had Hamilton depression scores that deviated from the response range (greater than 10 but less than 15).

The first planned step of the data analysis involved dividing the study group into subgroups who either relapsed or remained well, as we have described. Second, the pretreatment demographic and clinical characteristics of these groups were compared using Fisher's exact probability test, chi-square test, or Student's *t* test, as appropriate for categorical or continuous variables. Given the exploratory nature of these analyses, we used two-tailed tests but did not correct for the "inflation" of the alpha rejection factor that is associated with performing such multiple comparisons. Third, we compared the patients who relapsed and the patients who remained well with respect to end-of-treatment symptom status and speed of response to acute treatment (i.e., number of weeks from the onset of therapy until the patient first met the response criteria). Finally, the risk of relapse during the 12-month follow-up for the recovered and partially recovered groups was compared using survival analysis of life table data and tested with Wilcoxon's chi-square statistic.

RESULTS

Forty-nine of the 50 patients who were enrolled completed all scheduled visits during the 1-year follow-up program; the remaining patient dropped out after 6 months. A total of 16 patients (32%) relapsed. The patients who relapsed did not differ from those who remained well on most demographic variables, including age, sex, age at onset of the first episode of depression, and mean number of previous depressive episodes (table 1). However, patients who relapsed were significantly less likely to be married: 31% (*N*=5) of them were married, compared to 65% (*N*=22) of the patients who did not relapse ($\chi^2=7.32$, *df*=2, *p*<0.05). There was a trend for those who relapsed to have had at least one previous episode of major depression (table 1). The relapsers also had significantly higher pretreatment scores on the Hamilton depression scale, the Beck Depression Inventory, and the Dysfunctional Attitude

Scale, although the between-group difference on the GAS did not reach statistical significance (table 1).

At the end of treatment, patients who subsequently relapsed continued to have significantly higher residual scores on the Hamilton depression scale and the Dysfunctional Attitude Scale (table 1). A similar trend in posttreatment scores was apparent on both the GAS and the Beck Depression Inventory, although neither finding reached significance after adjustments for heterogeneity of variance (for both, adjusted *p*=0.06) (table 1). Patients who subsequently relapsed also showed a significantly longer time to response during acute treatment, with an average of more than 3 weeks of additional therapy received before response criteria were fulfilled (table 1). Finally, only 9% (*N*=2) of the patients who met the criteria for full recovery by the time of treatment termination subsequently relapsed, compared to 52% (*N*=14) of the partially recovered patients (Wilcoxon $\chi^2=10.63$, *df*=1, *p*=0.004) (figure 1).

Because of the association between a number of patient characteristics and risk of subsequent relapse, the survival analysis was repeated using the Cox proportional hazards regression model (21), which allows the relationship of the time elapsed to a categorical endpoint, such as relapse, to be modeled with respect to the influence of both independent variables and covariates. Patient characteristics often are entered as covariates, and covariates may be either continuous or categorical variables. The hazard function represents the probability of the outcome in question (for instance, relapse) per unit of elapsed time in follow-up. With the Cox model, the influence of a series of variables on the hazard function can be determined, both singly and in combination, using a stepwise multivariate analysis. As with any multivariate procedure, it is important to have a sufficient number of subjects for each variable studied. With 50 subjects, we chose five covariates of particular interest: time to response, marital status (married versus other), history of past episodes (yes versus no), posttreatment Hamilton depression scale score, and posttreatment Dysfunctional Attitude Scale score. Using the proportional hazards regression model, we tested each of the five covariates independently after adjusting for the other four effects. This method was used because of the unbalanced nature of the data. Both time to response ($\chi^2=6.18$, *df*=1, *p*=0.01) and marital status ($\chi^2=4.4$, *df*=1, *p*=0.03) were statistically related to the hazards function and contributed additively to prediction of outcome. Posttreatment score on the Dysfunctional Attitude Scale was a marginally significant covariate when other effects were controlled. Neither a history of past episodes ($\chi^2=2.34$, *df*=1, *p*=0.13) nor pretreatment Hamilton depression scale score ($\chi^2=1.55$, *df*=1, *p*=0.21) was statistically significant after accounting for the other effects ($\chi^2=3.04$, *df*=1, *p*=0.08). When a model using time to response, marital status, and posttreatment score on the Dysfunctional Attitude Scale was studied, the analysis yielded a significant relation to risk of relapse (global $\chi^2=12.85$, *df*=3, *p*=0.005).

During the 1-year follow-up, only five patients who

did not meet the full criteria for relapse met any of the "softer" criteria for relapse (transient or minor depression, return to treatment, and/or Hamilton depression scale score higher than 10 but lower than 15). Reassignment of these patients to the group of relapsed patients did not alter any of the findings of significance.

DISCUSSION

The 32% rate of relapse into depression observed during the 1-year prospective follow-up protocol is generally consistent with the rates reported by other investigators studying outcome after cognitive behavior therapy (3–6). Unlike several of the earlier follow-up studies (3, 4), however, our protocol included certain methodological refinements, such as use of regularly scheduled and standardized independent assessments, operationalized diagnostic criteria to define relapse, and maximal control over reentry into treatment. These features increase confidence in the ascertainment of cases of relapse. Of course, in the absence of appropriate control groups, we are not able to comment on whether acute cognitive behavior therapy actually lowered the inherent risk of relapse for our patients, particularly compared to patients treated with antidepressant medications or other forms of psychotherapy.

Patients who subsequently relapsed were more likely to be unmarried, tended to be suffering from a recurrent episode of depression, and reported higher levels of depressive symptoms and dysfunctional attitudes when they entered the study. They also ended acute treatment with higher levels of residual symptoms and had a slower response during therapy. Furthermore, the relatively straightforward division of the study group into recovered and partially recovered subgroups yielded a

highly significant association with subsequent outcome, with the partially recovered patients having a more than five times greater risk of depressive relapse than the fully recovered patients. Thus, although the findings of statistical significance may have been inflated somewhat by the exploratory nature of the univariate analyses, the results are consistent with those of earlier studies (3–9) and, with respect to the risk of relapse in partially recovered patients, they are both clinically relevant and robust.

Cognitive behavior therapy differs from other psychotherapies developed for depression, in part, because the final sessions of therapy are devoted to preparing for the possibility of relapse (1, 22). Patients treated with cognitive behavior therapy are encouraged to learn to identify or anticipate situations or problems that may increase their risk of relapse, and they spend time in therapy addressing these issues. Further, patients are asked to assume progressively more responsibility for independent application of therapeutic techniques during the final weeks of treatment, so that they can continue to use cognitive behavior therapy self-help methods long after termination of treatment (1, 22). It is of interest, therefore, that the relapse rates of the recovered and partially recovered subgroups did not begin to diverge until about 3 months after the end of therapy. Indeed, only about 10% of the patients in both the fully and the partially recovered subgroups relapsed during the first 2 months of follow-up. Thus, the difference in relapse rates between these subgroups does not appear to have been due to a rapid deterioration of clinical status immediately after withdrawal of the therapist's support and input. Rather, we suggest that many partially recovered patients struggle for at least several months to continue to apply techniques learned in therapy to cope with residual symptoms or psychosocial problems before ultimately relapsing into an episode of major depression.

During pharmacotherapy of unipolar major depression, a period of at least 4 months of continuation therapy after an acute response to drug treatment is now routinely recommended in order to reduce the risk of relapse (8, 9). For acutely depressed patients who respond rapidly to an antidepressant medication of first choice, the minimum course of treatment is thus about 5 or 6 months long. By contrast, an extended course of maintenance pharmacotherapy is typically recommended for patients who have experienced multiple episodes of depression or for those who manifest residual depressive symptoms despite continuation pharmacotherapy (8, 9). From this perspective, the 4-month course of cognitive behavior treatment provided in the Psychobiology of Recovery in Depression project protocol approximates the length of time usually spent in both the acute and continuation phases of pharmacotherapy for acute, uncomplicated major depression. Therefore, it is interesting that the 52% relapse rate documented in our partially recovered patients is so similar to the 40%–60% risk of relapse observed when medication responders do not re-

ceive an adequate period of continuation pharmacotherapy (8, 9).

Other investigators have documented the significance of a slow response to initial treatment or higher levels of residual symptoms in predicting relapse of patients with unipolar depression (3, 5, 6, 20, 23, 24). The relation between residual symptoms and recurrence of depression appears to be attenuated or even eliminated when a longer period of continuation pharmacotherapy is provided (25). We are not yet able to ascertain whether our partially recovered and fully recovered patients differed only with respect to general prognostic factors (higher levels of residual symptoms, slower response to initial therapy, greater past history of depression, and/or lower levels of social support) or whether they also differed on variables that reflect the process and course of therapy (the strength of the therapeutic alliance, compliance with homework assignments, and/or the technical quality of the therapist's interventions). It also may be useful to try to differentiate between the partially recovered patients who relapsed and those who did not. Nevertheless, we consider the 52% relapse rate of the partially recovered patients to be a clear indication for the need to develop, implement, and test alternative methods for treating such patients. Further, it seems likely that if patients with so-called "double depression" had been enrolled in our study, the relapse rate would have been even higher (20).

We therefore recommend that patients who do not fully recover from a depressive episode after time-limited psychotherapy should be considered for either more extended therapy or for other treatment modalities. One such revised treatment plan would consist of prolonging the course of weekly cognitive behavior therapy until the patient meets criteria for recovery. For some patients, this recommendation could entail a 6-, 9-, or even 12-month course of therapy. Alternatively, an ongoing but less intensive approach of maintenance psychotherapy might prove useful. In our clinical practices, we sometimes provide a period of several months of biweekly visits, followed by a number of monthly sessions, to patients considered to be at high risk for relapse. With respect to the efficacy of maintenance psychotherapy, Frank et al. (25) recently demonstrated the value of monthly sessions of interpersonal psychotherapy (relative to a placebo-treatment control group) in a study of patients with highly recurrent forms of unipolar depression.

On the other hand, it might be suggested that patients who manifest residual symptoms after short-term cognitive behavior therapy have more virulent or "endogenomorphic" forms of depression which, perhaps, would be treated more appropriately by pharmacotherapy than by additional sessions of psychotherapy. Beyond the work of Elkin et al. (26) and our own previous report linking greater initial severity of depression with somewhat poorer absolute response to cognitive behavior therapy (11), we are not aware of strong empirical support for this hypothesis. Moreover, many of the partially recovered patients at risk for relapse in our study

ended treatment with Hamilton depression scale scores in the 3- to 8-point range, a level of symptoms that would not normally justify the initiation of pharmacological treatment.

It also seems clear that not all patients treated with cognitive behavior therapy would benefit from more extensive treatment. For example, the low (9%) risk of relapse among the fully recovered patients suggests that a great majority of patients who achieve such favorable acute outcomes during time-limited therapy continue to do well without additional treatment, at least during the first year after termination of therapy. Perhaps the low risk of relapse among fully recovered patients in the Psychobiology of Recovery in Depression study might explain why Baker and Wilson (27) found no evidence of protection from relapse when additional "booster" cognitive behavior therapy sessions were provided, unselectively, to a small sample of therapy responders.

In summary, a series of 50 patients who improved during a time-limited course of cognitive behavior therapy were enrolled in a systematic, longitudinal, 1-year follow-up protocol. A number of clinical correlates of subsequent relapse were identified, and parallels were drawn between the risks of depressive relapse after time-limited psychotherapy and those after a short-term course of antidepressant pharmacotherapy. As in pharmacotherapy of unipolar depression, we suggest that longer-term models of continuation and/or maintenance psychotherapy may be necessary for selected patients at high risk for relapse or recurrence.

Protective Effects of Imipramine Maintenance Treatment in Panic Disorder With Agoraphobia

Matig Mavissakalian, M.D., and James M. Perel, Ph.D.

Objective: This study was designed to assess and compare the differential relapse rates of patients with panic disorder and agoraphobia after discontinuation of acute treatment (6 months) or acute plus maintenance treatment (18 months) with imipramine. **Method:** Sixteen patients with panic disorder and agoraphobia who had shown marked and stable response to 6 months of acute imipramine treatment and a comparable group of 14 patients who had been in remission during an additional year of half-dose imipramine maintenance treatment entered a 3-month, double-blind discontinuation study followed by a 3-month drug-free period. Assessments of the patients were made according to operationalized response/relapse criteria, and plasma drug concentrations were monitored. **Results:** Survival analysis revealed significantly different cumulative probabilities of continued response 6 months after discontinuation of imipramine treatment between the patients who had received only acute treatment and those who had received acute and maintenance treatment. **Conclusions:** The results support the hypothesis that successful imipramine maintenance treatment of patients with panic and agoraphobia can have protective effects against relapse, at least in the first 6 months after the maintenance treatment period.

(Am J Psychiatry 1992; 149:1053-1057)

Patients with panic disorder and agoraphobia, like those suffering from obsessive-compulsive disorder (1) and unipolar depression (2), are likely to relapse when pharmacotherapy with antidepressants is discontinued (3-6). Recently, we reported (7) that approximately 75% of patients with panic disorder and agoraphobia who had shown marked and stable response to 6 months of acute treatment with imipramine relapsed within 6 months of discontinuing the drug. In contrast, none of the patients from a similarly treated sample who had responded to imipramine and who had received maintenance treatment with the drug for 12 additional months (at one-half the dose they received during acute treatment) relapsed or had sustained worsening of panic or phobic symptoms throughout the 1-year maintenance period. In the present study we explored the potential protective effects of imipramine maintenance treatment against relapse in these two samples by comparing the cumulative relapse rates 6

months after discontinuation of acute imipramine treatment and 6 months after discontinuation of acute plus maintenance imipramine treatment. Studies of monoamine oxidase inhibitors (MAOIs) in mixed anxiety-phobic diagnostic groups (8, 9) have suggested that although there is still substantial relapse, it is less among patients who discontinue drug treatment after 1 year than among those treated for 6 months or less.

METHOD

The experimental groups of the present study were derived from the consecutive samples previously studied (7). One group consisted of 16 patients who entered the discontinuation protocol immediately after acute imipramine treatment (the acute group). The other consisted of 14 patients (of the 19 who participated in the maintenance study) who entered the discontinuation protocol upon successful completion of 1 year of imipramine maintenance therapy at one-half the dose received during their acute treatment (the delayed group). The method of subject selection, the acute and maintenance treatments used, and the assessments of the patients have been previously described in detail (7, 10, 11).

Briefly, all of the subjects were outpatients meeting the DSM-III-R criteria for panic disorder with agoraphobia who had shown good and stable response to an open imipramine protocol at a dose of 2.25 mg/kg per

day over an initial 24-week acute treatment period. At week 8 of their acute treatment, patients were also given a behavioral rationale for self-directed exposure to phobic situations and a programmed practice manual to read and apply to their situations (12). No additional sessions for monitoring self-directed practice of exposure were offered. Thus, the behavioral therapy input was limited to providing all patients with the same information regarding exposure. Patients were assessed after 16 and 24 weeks of acute treatment, and the first consecutive 19 patients who met operationalized criteria for responder status at both assessments participated in the prospective 1-year open maintenance study at one-half the imipramine dose received during acute treatment. No additional treatment for agoraphobia or panic was provided during the maintenance phase, which was successfully completed by 14 patients without a single relapse. (The noncompleters did not differ significantly from the 14 completers on demographic or clinical variables before acute treatment and were responders up to the point of dropping out of the maintenance study.) These 14 patients formed the delayed experimental group of the present study. The next 16 consecutive patients who met the operationalized criteria for responder status consented to participate in the discontinuation protocol immediately after their 24-week acute treatment assessment (the acute group).

Because the present study group of 30 patients was derived from two groups of responders who had been consecutively rather than randomly assigned to maintenance and acute treatment groups, we performed 2x2 Group by Time (pretreatment and end of active treatment) analyses of variance (ANOVA) on the seven major outcome measures, described below, to ensure that the groups were comparable in initial severity of illness and response to acute treatment. As expected, there were significant time effects on all measures but no main effects of group, which would have indicated different overall levels of severity. It is also noteworthy that, with one exception, there were no Group by Time interactions, indicating that the groups improved equally during acute treatment. The exception was in clinician-rated severity of panic and reflected the slightly higher pretreatment ratings of the acute group: the pretreatment and end-of-treatment mean ratings were 2.6 (SD=0.7) and 0.2 (SD=0.4), respectively, for the acute group and 2.1 (SD=0.3) and 0.4 (SD=0.5), respectively, for the maintenance group ($F=5.03$, $df=1, 25$, $p=0.03$).

The mean age of the total study group was 34.2 years (SD=8.0); their mean number of years of education was 13.9 (SD=2.1). Sixty-seven percent ($N=20$) of the patients were female, 60% ($N=18$) were married, and 70% ($N=21$) were currently employed. The average age at onset of panic disorder was 27.9 years (SD=6.7), and the average duration of illness was 6.4 years (SD=6.3). There were no concurrent diagnoses of major depression or substance abuse; however, 27% ($N=8$) of the patients had histories of past major depression, and 17% ($N=5$) had histories of past substance abuse. Patients in the delayed group

were significantly older (mean age=38.1 years, SD=8.0) than those in the acute group (mean=30.7 years, SD=6.2) ($t=2.86$, $df=28$, $p=0.01$), and they had a longer duration of illness (mean=9.1 years, SD=7.9) than the acute group (mean=4.1 years, SD=3.3) ($t=2.30$, $df=28$, $p=0.03$). The stable imipramine dose received during acute treatment was not significantly different for the two experimental groups and averaged 2.1 mg/kg per day (SD=0.3) (mean=145.8 mg/day, SD=35.4) for the group as a whole.

The design of the present study consisted of a 3-month double-blind drug discontinuation phase followed by a 3-month drug-free follow-up period. The study was initiated (month 0) by converting from open prescription of imipramine to double-blind administration of four identical-looking tablets containing either placebo or 10, 25, 50, or 75 mg of imipramine hydrochloride. The drug condition for each patient was known only by the hospital pharmacist, who followed a procedure to ensure equal distribution of placebo ($N=8$) and imipramine ($N=8$) in the acute group and an assignment ratio of three patients receiving placebo ($N=10$) to one patient receiving imipramine ($N=4$) in the delayed group. Those assigned to imipramine received the same dose, or extremely close to it, for 3 months. Discontinuation was achieved by 25% decrements each week, so that a zero imipramine dose (four placebo tablets) was reached on the 22nd day of randomization. Patients were instructed, indeed encouraged, to contact us for any psychiatric or psychological problems that they might have, with the understanding that they would be seen immediately and appropriate clinical action would be taken. Otherwise, they were assessed on a monthly basis for 3 months, when the drug code was broken. A concerted effort was made to follow patients in the placebo condition who had not relapsed for an additional 3-month drug-free period.

The same battery of tests that had been used to determine all patients' response status during acute treatment and the delayed group's status during maintenance treatment (7) was used in the present study. Responders were operationally defined as those who 1) showed a simultaneous reduction of 50% or more from pretreatment values on six or all seven of the response measures or 2) had scores that signified minimal or absent symptoms, as follows: score of 2 or less on the Global Assessment of Severity Scale, score of 2 or less on the Self-Rating Scale of Severity of Phobias, score of 10 or less on the Agoraphobia subscale of the Fear Questionnaire, score of 2 or less on the Phobic Anxiety and Avoidance Scale, score of 2 or less on the Behavioral Assessment Test, panic severity rating of 2 or less by the patient, and panic severity rating of 1 or less by the clinician. For this study relapse was defined a priori as meeting no more than four of these criteria and requiring or requesting treatment for panic or agoraphobia. (Detailed descriptions of the seven dependent measures are given elsewhere [7, 10, 11].)

At each assessment blood samples were drawn 12 hours after the preceding dose and collected into plasticizer-free Vacutainers. The samples were promptly

centrifuged and stored at -20°C for later determination of drug concentrations by a modified high-performance liquid-chromatography technique (10, 13, 14).

RESULTS

All 30 subjects were responders at the time they were randomly assigned to the study groups. As a further check on randomization, ANOVAs with the two groups (acute, delayed) and two conditions (imipramine, placebo) were performed on the seven dependent measures at month 0. No significant main effects of condition or interaction effects were found, although, as could be expected from the consolidation of improvement previously reported during the 1-year half-dose maintenance protocol (7), statistically significant group main effects emerged for scores on the Self-Rating Scale of Severity of Phobias and the Agoraphobia subscale of the Fear Questionnaire; the delayed group had slightly lower scores on these two measures. As expected, the dose of imipramine was significantly different for the acute and delayed groups (mean=2.04 mg/kg per day, SD=0.23, and mean=1.07 mg/kg per day, SD=0.10, respectively; $t=14.38$, $df=28$, $p<0.01$).

Analysis of monthly plasma levels revealed tricyclic concentrations of 0 ng/ml in all patients assigned to placebo. Repeated measures ANOVAs on plasma data for month 0 through month 3 of the patients assigned to the imipramine continuation condition did not reveal significant effects of time on total tricyclic levels or plasma level/dose ratios, indicating generally good compliance with the experimental conditions. The average total tricyclic levels, according to all available plasma data from patients in the imipramine condition, were 158 ng/ml (SD=57.0) and 55 ng/ml (SD=26.6) for the acute and delayed groups, respectively.

With one exception, none of the patients assigned to

FIGURE 1. Six-Month Survival Curves of Patients With Panic Disorder and Agoraphobia After Discontinuation of 6 Months of Acute Imipramine Treatment (Acute Group) or 6 Months of Acute Plus 1 Year of Maintenance Imipramine Treatment (Delayed Group)

imipramine in the double-blind phase of the study relapsed. The exception occurred in the acute group during the second month of the protocol, at the time of a patient's increased distress due to exacerbation of her husband's medical condition. The drug code was broken and the patient continued to take study medications for another month, when she was again a responder.

Table 1 shows relapse rates within 6 months of imipramine discontinuation for the acute and delayed groups assigned to placebo. Because four of the 14 survivors from the double-blind placebo phase were lost to follow-up in the subsequent 3-month drug-free period, we used three scenarios to estimate 6-month cumulative relapse rates. As can be seen in table 1, the frequency of relapse in the acute group consistently exceeded that of the delayed group by a ratio of 2 or 3 to 1. For statistical analysis of the data we used the Kaplan-Meier product limit method to estimate and the Mantel-Cox method to compare the 6-month survival curves in the acute and delayed placebo groups (15). The results are illustrated in figure 1 and show that the cumulative probability of continued response 6 months after discontinuation of imipramine was 0.21 in the acute group (mean survival of 3 months) and 0.77 in the delayed group (mean survival of 5.2 months). Comparison of the observed test statistic, $\chi^2=4.06$, with a chi-squared distribution value of 3.84, with 1 degree of freedom ($p=0.05$), leads to rejection of the null hypothesis that the two curves are the same.

Of the five observed relapses in the acute placebo group, one occurred within 1 month of discontinuation, two during the third month of the discontinuation study, and two during the fifth month of the study. One of the patients in the delayed group relapsed during the third month and the other relapsed during

the sixth month of the study. The relapse of these seven patients is characterized in table 2. It can be seen that both phobic and panic symptoms became substantially worse and that ratings of panic severity returned to pre-treatment levels. The pattern of change was the same in individual patients, and all of them were having panic attacks at the time of relapse. The patients who relapsed clinically required and personally requested resumption of imipramine treatment. None of them met diagnostic criteria for major depression at the time of relapse.

DISCUSSION

Panic disorder with agoraphobia is a prevalent syndrome (16), and imipramine is the standard nonbenzodiazepine pharmacotherapy, yielding approximately 75% marked response rates when it is the sole or main treatment (11, 17). Reported relapse rates after discontinuation of imipramine (or MAOIs) vary from 17.5% to 100%, partly reflecting varying definitions of relapse, which are often unspecified, and partly reflecting varying dosages and duration of treatment or degrees of improvement/response before drug discontinuation (3–5). The present study offers clear methodological advantages in this respect. The subjects consisted of two consecutive groups of homogeneously selected and uniformly treated patients with panic disorder and agoraphobia who had shown marked and stable response to 6 months of acute treatment with imipramine. Furthermore, operationalized criteria for response and relapse were uniformly applied, discontinuation of imipramine for the first 3 months of the study was double-blind, and the use of plasma drug level determinations verified the integrity of experimental drug conditions.

The salient difference between the otherwise compa-

rable acute and delayed groups—namely, the additional successful maintenance therapy received by the latter—was the experimental variable of interest in our investigation of the potential effects of maintenance therapy as protection against relapse. Thus, although determination of the exact magnitude of the problem of relapse after discontinuation of imipramine treatment should await large-scale, double-blind studies over longer periods of time, the differential relapse rates of the acute and delayed groups in the present study support the hypothesis that 1 year of successful imipramine maintenance treatment at one-half the dose received during acute treatment can have protective effects against relapse, at least in the first 6 months after the maintenance treatment period. Whether this protective effect continues for longer periods of time and whether longer durations of imipramine maintenance therapy would have greater and more enduring protective effects in patients with panic disorder and agoraphobia are empirical questions worthy of study.

Because none of the patients in the delayed group had received other specific treatments for panic/agoraphobia during maintenance therapy, and in light of the high relapse rate in the acute group, we have suggested that the stability of gains during the open maintenance treatment period was due primarily, if not specifically, to continued exposure to imipramine (7). Whether the reduced imipramine dose during maintenance treatment contributed, significantly and independently of duration of remission, to the protective effects against relapse upon discontinuation of imipramine remains an interesting and important question to be elucidated. It is unlikely that the mechanisms involved in the differential relapse rates were related to withdrawal, since no patient reported difficulty or untoward effects in the first 3 weeks of gradual discontinuation of imipramine, and only one of the relapses occurred during the first month of the study. It is possible, however, that excessive down-regulation of putative β -adrenergic and serotonergic receptors was moderated through the administration of the half-doses (as compared to full doses) of imipramine during maintenance treatment. There is clear experimental evidence that imipramine, in a dose-dependent fashion, reduces the density of β -adrenergic receptors in the cerebral cortex (18).

The Latent Structure of Anxiety Symptoms in Anxiety Disorders

Justin Kenardy, Ph.D., Larry Evans, M.B.Ch.B., D.P.M., and Tian P.S. Oei, Ph.D.

Objective: Research in the psychopathology of panic and anxiety disorders, particularly agoraphobia, suggests that fear of fear may be the basis of these conditions. However, there is little empirical research on the definition and validity of the concept of fear of fear in a clinical study group. The authors' aims are 1) to determine empirically if particular associations between symptoms and beliefs exist in a group of patients with anxiety disorders and what underlying dimensions of perceived threat they represent and 2) to assess the relative importance of these associations in agoraphobia with panic attacks, panic disorder, social phobia, and generalized anxiety disorder. **Method:** In an anxiety disorders treatment unit, 390 outpatients with anxiety disorders diagnosed according to DSM-III criteria completed the Anxiety Symptoms and Beliefs Scale. **Results:** A principal components analysis of the patients' ratings on the Anxiety Symptoms and Beliefs Scale produced a four-factor solution in which specific sets of anxiety symptoms loaded with specific beliefs. These four factors were interpreted as respiratory symptoms, vestibular symptoms, autonomic arousal, and psychological threat. Respiratory and vestibular symptoms were more associated with panic disorder diagnoses than with social phobia and generalized anxiety disorder diagnoses. **Conclusions:** These findings support a conception of fear of fear in anxiety disorders as fearful beliefs concerning the experience of anxiety symptoms. Associations between symptoms and fear of fear are present across anxiety disorders but are most pronounced in agoraphobia with panic attacks.

(Am J Psychiatry 1992; 149:1058-1061)

By making agoraphobia secondary to a diagnosis of panic disorder, *DSM-III-R* elevated the status of panic attacks in clinical presentation. An important change made to the new diagnostic criteria for panic disorder has been the optional waiving of the frequency criterion of four panic attacks in a 4-week period. The alternative criterion requires that "one or more attacks have been followed by a period of at least a month of persistent fear of having another attack." This criterion recognizes the importance of fear of panic attacks, or fear of fear.

The concept of fear of fear in agoraphobia and panic disorder is not new (1-4). Goldstein and Chambless (4) conceived the core of agoraphobia as the fear of harmful consequences of experiencing anxiety symptoms. Subsequently, Chambless et al. (5) developed companion

measures of fear of fear called the Body Sensations Questionnaire and the Agoraphobic Cognitions Questionnaire. More recently, Reiss and McNally (6) proposed a formulation of fear of fear as the dual-component processes of anxiety expectancy and anxiety sensitivity. Anxiety expectancy is the expression of the learned association between anxiety symptoms and fear. Anxiety sensitivity is the belief that anxiety and anxiety symptoms are dangerous. This belief was seen as underlying anxiety in general. Thus, associations of specific symptoms and beliefs were not thought to be important in the presentation of fear of fear; rather, fear of harmful consequences of any type of anxiety symptom or anxiety in general was seen to underlie anxiety.

Beck et al. (7) suggested that particular feared outcomes maintain particular anxiety disorders. For example, perceived threats to physical and mental health are seen as central to agoraphobia, whereas perceived threats to social acceptability and performance are associated with social phobia. Studies to date have examined the construct of fear of fear either by measuring symptoms and beliefs separately (5) or by arbitrarily attaching symptoms to particular consequences (8). Further, there has not been any empirical evidence supporting the validity of associations between symptoms and beliefs as expressions of fear of fear.

The aims of this study were 1) to determine empirically if particular associations between symptoms and beliefs

exist in a group of patients with anxiety disorders and what underlying dimensions of perceived threat they represent and 2) to assess the relative importance of these associations in agoraphobia with panic attacks, panic disorder, social phobia, and generalized anxiety disorder.

METHOD

Subjects

Of 529 patients who came sequentially to an anxiety disorders clinic between 1981 and 1987 for assessment and treatment in an intensive group cognitive-behavioral program, 390 who met *DSM-III* criteria for one of four anxiety disorder diagnoses were selected for study. Fifty-three of these patients had panic disorder, 246 had agoraphobia with panic attacks, 54 had social phobia, and 37 patients had generalized anxiety disorder. The patients who had the *DSM-III* diagnosis of agoraphobia with panic attacks also met *DSM-III-R* criteria for panic disorder with agoraphobia. Table 1 presents the characteristics of the study group. The sex ratio did not differ among groups ($\chi^2=4.21$, $df=3$, n.s.), although women were in the majority in each group (table 1). The patients with agoraphobia with panic attacks and those with generalized anxiety disorder were significantly older than the patients with social phobia ($F=5.55$, $df=3$, 384, $p=0.001$). The mean age at onset was not significantly different across groups ($F=2.24$, $df=3$, 328, n.s.).

Measures

The Anxiety Symptoms and Beliefs Scale was adapted from the Agoraphobia Survey Schedule (9). For example, the fear of starting to scream was excluded because in our clinical experience this is rarely reported as a belief. The instrument assesses the intensity on a 5-point scale of 16 symptoms of extreme anxiety and five beliefs (fears) concerning the consequences of panic. The symptoms include those prescribed by *DSM-III* and *DSM-III-R* as constituting a panic attack.

Procedure

The procedure for assessment and diagnosis has been fully described elsewhere (10). After referral, patients

TABLE 2. Intercorrelations Between Rotated Factors for 335 Patients With Anxiety Disorders

Factor	Correlation (r)		
	Factor 1	Factor 2	Factor 3
Factor 1 (vestibular symptoms)			
Factor 2 (respiratory symptoms)	0.30		
Factor 3 (psychological threat)	0.33	0.24	
Factor 4 (autonomic arousal)	0.44	0.55	0.37

completed the Anxiety Symptoms and Beliefs Scale. Subsequently, the patients participated in a structured interview with a staff psychiatrist or clinical psychologist skilled in assessment and diagnosis of anxiety disorders using *DSM-III* criteria. The interview lasted about 1.5 hours during which a life history was taken, self-report forms were reviewed with the patient, and clinical rating scales were administered. The case history was then presented to a meeting of all clinical staff and a diagnosis was determined. All patients provided informed consent to their participation in the study.

RESULTS

To assess the underlying association between the physical anxiety symptoms and the belief items a principal components analysis was performed on the patients' ratings of the 21 items of the Anxiety Symptoms and Beliefs Scale. The number of patients included in the analysis was 335 after listwise deletion of missing values was applied. The number of factors was determined by applying the criterion of an eigenvalue greater than 1.0. Further inspection of eigenvalues revealed a substantial break in the percentage of variance between the fourth and fifth components and a gradual decline in variance thereafter. The four-factor principal axis solution was chosen, and this accounted for 45.2% of the variance. Orthogonal and oblique rotations were applied to the solution, and inspection for the factor plots and the correlations between factors (table 2) suggested an oblique rotation was most appropriate. The factor pattern matrix is presented in table 3.

Inspection of the factor loadings (table 3) revealed that each factor had loadings for both the physical anxiety symptoms and the beliefs (fears). For factor 1, all items were associated with symptoms of faintness, diz-

TABLE 3. Factor Loadings and Communalities for Rotated Factors for 335 Patients With Anxiety Disorders

Symptom or Belief (Fear)	Factor				Communality

Nausea	-0.01	0.16	-0.10	0.44	0.26

ziness, lightheadedness, and the feared consequence of fainting. This factor was labeled vestibular symptoms. The second factor had loadings for symptoms of respiratory disturbance and the fear of dying. All symptoms here could be interpreted as indicating threat to life. This factor was labeled respiratory symptoms. The third factor was made up of "unusual" symptoms of depersonalization and derealization plus with the fear of going crazy, losing control, and looking foolish. Beck et al. (7) suggested that an association between these apparently strange and uncontrollable anxiety symptoms and fear of loss of sanity and control should be found in panic attacks. This factor was labeled psychological threat. For the fourth factor, most of the symptoms were susceptible to external scrutiny, for example, flushes, sweating, and trembling. This factor could be labeled autonomic arousal. The feared consequence of looking foolish also loaded, suggesting that this factor may encompass what Beck et al. (7) called "sociality threats."

To assess the relationships between the beliefs and symptoms further, correlations were performed between the individual beliefs associated with each factor and the factors minus that belief. The correlations were greatest for the fear of fainting with vestibular symptoms ($r=0.57$), followed by fear of losing control ($r=0.42$) and fear of going crazy ($r=0.40$) with psychological threat, fear of dying with respiratory symptoms ($r=0.34$), and fear of looking foolish with autonomic arousal ($r=0.30$) and with psychological threat ($r=0.25$).

Factor scores were developed from each of the four factors by adding the raw scores of the variables with loadings greater than 0.45 on each factor and dividing by the number of loading variables (11). A multivariate analysis of variance was performed for the factors

across diagnoses. A linear combination of factors was derived that was significantly affected by diagnosis according to Wilks's lambda ($F=4.78$, $df=12$, 868, $p<0.001$). The canonical loadings for the single significant root ($\chi^2=55.87$, $df=12$, $p<0.001$) are presented in table 4. The largest weightings were for vestibular symptoms and faintness. A post hoc comparison between the diagnoses of panic disorder and agoraphobia revealed no significant differences on this linear combination ($F=1.48$, $df=4$, 331, n.s.), but a significant difference was found between the panic disorder and the non-panic-disorder diagnoses ($F=4.98$, $df=4$, 331, $p<0.001$).

DISCUSSION

This study provides support for a definition of fear of fear as catastrophic beliefs associated with the symptoms of anxiety. Unlike study groups used in other research in this area (8, 12), our subjects were clinic outpatients with anxiety disorders. Also, unlike other studies of fear of fear (5, 13), the present study found underlying dimensions of fear of fear suggesting that different fears are related to particular symptom clusters. The results do not support the findings of Reiss et al. (8) that fear of fear as assessed by the Anxiety Sensitivity Index is unidimensional. Rather, they are consistent with the finding of multidimensionality on this scale by Telch et al. (14). Also, the Agoraphobic Cognitions Questionnaire (5) has two factors—social/behavioral concerns and physical concerns—that are similar to the dimensions of fear found on the Anxiety Symptoms and Beliefs Scale. Our findings are consistent with the conceptualization by Beck et al. (7) of threats to domains of potential vulnerability that underlie the

^bFrom MANOVA.

anxiety disorders, but they also suggest an extension in that particular symptom clusters are correlated with certain domains of threat and vulnerability.

Although the results show that the associations between symptoms and fears are present across the diagnoses of social phobia, generalized anxiety disorder, agoraphobia with panic attacks, and panic disorder, it appears that they are present in higher levels in agoraphobia. Fear of fear as assessed by the Anxiety Symptoms and Beliefs Scale is particularly severe for patients with agoraphobia with panic attacks. This is consistent with the views of Goldstein and Chambless (4) and Chambless et al. (5). More recently, Chambless and Gracely (15) found that fear of fear as assessed across anxiety disorder diagnoses by the Agoraphobic Cognitions Questionnaire and the Body Sensations Questionnaire was highest in agoraphobic subjects. One possible reason for this relationship is the association between fear of fear and avoidance (15, 16). It is possible that the extent of agoraphobic avoidance may represent the extent and severity of perceived threats and vulnerabilities. The relationship found between vestibular and respiratory symptoms and agoraphobia may be related to the more catastrophic outcomes associated with these symptoms. An agoraphobic patient who feels that experiencing respiratory symptoms leads to catastrophic physical outcomes may avoid situations where vulnerability to such threats would be high, such as crowds, shopping centers, public transportation, or places where help was not easily accessible. The same situations might also be avoided because of the threat to perceived social/behavioral competency but may not have the same level of threat associated with them. These results suggest that not all symptoms of anxiety are equally important to fear of fear. Vestibular symptoms and the fear of fainting and respiratory symptoms such as chest pain, difficulty breathing, and choking sensations, which could quite readily be misperceived as life-threatening, may be a part of the cluster of symptoms and beliefs associated with fear of fear. In contrast, trembling and shaking, which are obvious external expressions of lack of social adeptness, may be less open to catastrophic interpretation.

The limitation of this study is that it uses retrospective self-reports of anxiety symptoms in correlational analyses to investigate relationships between cognitive

appraisals of anxiety symptoms and fear. Furthermore, no conclusions can be drawn from these data with respect to the causal relationships that may exist among the physiological, cognitive, and affective components of fear of fear. It is possible that there are complex and dynamic relationships among anxiety symptoms, cognitions, and fears underlying the fear of fear in anxiety disorders (10).

Toward a Brain Map of Auditory Hallucinations

John M. Cleghorn, M.D., Sheryl Franco, R.N., Barbara Szechtman, B.A.,
Ronald D. Kaplan, Ph.D., Henry Szechtman, Ph.D., Gregory M. Brown, M.D., Ph.D.,
Claude Nahmias, Ph.D., and E. Stephen Garnett, M.D.

Objective: This study asks whether auditory hallucinations are reflected in a distinctive metabolic map of the brain. **Method:** Regional brain metabolism was measured by positron emission tomography with [^{18}F]-fluorodeoxyglucose in 12 DSM-III schizophrenic patients who experienced auditory hallucinations during glucose uptake and 10 who did not. All patients were free of neuroleptics and 19 had never been treated with neuroleptics. Nine patients were reexamined after 1 year to assess effects of neuroleptic treatment. **Results:** Compared with the patients who did not experience hallucinations, the patients who did experience hallucinations had significantly lower relative metabolism in auditory and Wernicke's regions and a trend toward higher metabolism in the right hemisphere homologue of Broca's region. Hallucination scores correlated positively and significantly with relative metabolism in the striatum and anterior cingulate regions. Neuroleptic treatment resulted in a significant increase in striatal metabolism and a reduced frontal-parietal ratio, which was significantly correlated with a decrease in hallucination scores. **Conclusions:** Auditory hallucinations involve language regions of the cortex in a pattern similar to that seen in normal subjects listening to their own voices but different in that left prefrontal regions are not activated. The striatum plays a critical role in auditory hallucinations.

(Am J Psychiatry 1992; 149:1062-1069)

In order to discover the neural basis of psychotic phenomena such as auditory hallucinations, the systems of the living brain involved in their occurrence must be identified. Auditory hallucinations, a salient feature of 70% of schizophrenic psychoses, may represent subvocal speech. The notion that auditory hallucinations might reflect the subjects' own speech was suggested by the observation that the reported content of hallucinations corresponded with that recorded through a microphone held to the mouth (1). The fact that auditory hallucinations can be interrupted by opening the mouth very wide, thus preventing vocalization, suggests that the hallucinations are expressed by the subject's larynx

(2). We examined regional brain glucose metabolism in chronic schizophrenic subjects with persistent hallucinations (N=9) and compared them with a matched group of patients (N=10) and normal control subjects (N=10) (3). We reported that correlations between metabolism in certain language regions were significantly different in the hallucinating group than in the nonhallucinating group and control subjects. Hallucination scores correlated positively and significantly with relative metabolism in the anterior cingulate region. All patients were taking neuroleptic medications.

In the present study we examined metabolic activity in language regions of the brain (figure 1) with positron emission tomography (PET) using [^{18}F]-fluorodeoxyglucose (FDG) in 22 drug-free schizophrenic patients who experienced auditory hallucinations; 19 of the patients had never been treated with antipsychotic drugs. Twelve of the patients reported hearing voices during the period in which FDG was being taken up in the brain, and 10 did not. Thus, the relative regional metabolism of the brain was pictured and measured during the fortuitous occurrence of hallucinations in one group of patients, while in the other group, the voices were quiescent during the examination. Using unmedicated subjects, we could thus reexamine the hypothesis that hallucinatory events involve the language regions of the brain.

Presented at a new research session at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. Received Nov. 6, 1990; revision received Jan. 8, 1992; accepted Feb. 7, 1992. From the Departments of Psychiatry and Biomedical Sciences, McMaster University; the Department of Psychiatry, University of Toronto, Toronto, Ont.; and the Department of Nuclear Medicine, Chedoke-McMaster Hospitals, Hamilton, Ont. Address reprint requests to Dr. Szechtman, Department of Psychiatry, McMaster University, 1200 Main St. West, Hamilton, Ont., Canada L8N, 3Z5.

Dr. Cleghorn died June 8, 1992.

FIGURE 1. Three Slice Levels of the Brain Examined in 22 Schizophrenic Patients With and Without Auditory Hallucinations During PET Scan^a

^aLow: orbitofrontal-superior temporal including auditory cortex and an inferior part of Wernicke's region—inferior parietal; middle: prefrontal including Broca's region—parietal; high: prefrontal-supramarginal and parietal.

METHOD

Patients

We recruited patients from the emergency and outpatient services who met presumptive *DSM-III-R* criteria for schizophrenia. They were then admitted to the hospital and followed as outpatients for at least 1 year. Patients with a history of neurological disorder and major medical illness were excluded. Detailed developmental histories were obtained from family members. Histories included the onset of negative and later positive symptoms; this information, when combined with follow-up data, permitted the diagnosis of schizophrenia by *DSM-III* criteria.

It should be understood that the patients classified as not having hallucinations had experienced hallucinations at various times before the procedure. The mean age of the patients who did experience hallucinations during PET scan was 24.2 years ($SD=7.4$). Eight were men and four were women. Nine patients were reexamined after 1 year of neuroleptic treatment. Five had hallucinated during the scan, but all had auditory hallucinations before and after the scan. The patients who did not experience hallucinations during PET scan had a mean age of 29.5 years ($SD=9.7$). Eight were men and two were women. All but three patients were right-handed. The two left-handed patients and one mixed-handed patient were in the group that experienced hallucinations. Only two patients who did not and one patient who did experience hallucinations had in the past been treated with neuroleptic medications, and they had been drug free for many months before the study.

All patients had been ill for 6 months or more, some for many years. There was no significant difference between the groups' length of illness: the mean for patients who did experience hallucinations was 4.5 years

TABLE 1. Demographic Characteristics of Schizophrenic Patients With and Without Auditory Hallucinations

Item	Hallucinating Subjects (N=12)		Nonhallucinating Subjects (N=10)	
	Mean	SD	Mean	SD
Age (years)	24.2	7.4	29.5	9.7
Education (years) ^a	11.1	1.8	13.0	2.2
Length of medication (years)	0.8	2.6	1.0	2.1
Age at onset of schizophrenia (years) ^b	18.8	2.9	23.6	4.5
Length of illness (years)	4.5	5.5	5.9	5.8
Number of episodes	1.3	0.6	1.2	0.6
Use of street drugs ^c	1.2	0.8	1.0	0.8
Performance IQ ^d	98.1	14.6	105.4	12.6
Memory quotient ^e	81.6	18.8	99.4	17.2
Picture arrangement score ^f	7.7	2.5	10.9	3.1
SADS-C positive symptom scores ^g	3.0	1.0	1.9	1.0
SADS-C negative symptom scores ^h	4.3	0.8	2.0	0.8

^a $t=2.25$, $df=20$, $p=0.04$ (two-tailed test for all comparisons).

^b $t=3.00$, $df=20$, $p=0.007$.

^c1.0=prior substance abuse to a mild or moderate degree by *DSM-III* criteria.

^d $t=2.10$, $df=20$, $p=0.05$.

^e $t=2.31$, $df=20$, $p=0.03$.

^f $t=2.62$, $df=20$, $p=0.02$.

^g $t=2.80$, $df=20$, $p=0.01$.

^h $t=2.67$, $df=20$, $p=0.01$.

($SD=5.5$), and the mean for patients who did not experience hallucinations was 5.9 years ($SD=5.8$). However, the mean age at onset for the patients who did experience hallucinations was significantly younger than that of the patients who did not experience hallucinations during PET scan ($p=0.007$) (table 1).

The patients who experienced hallucinations also had significantly less education and a lower Wechsler performance IQ and memory quotient. Picture arrangement scores were significantly lower in the patients who experienced hallucinations (table 1). None of the 60 additional neuropsychological tests we used discriminated between groups. These measures are described in Cleg-horn et al. (4). Type I errors are possible here because of the large number of comparisons.

Both positive and negative symptoms were more severe among the patients who experienced hallucinations (table 1). The patients who experienced hallucinations had higher hallucination scores than those who did not experience hallucinations when measured before scanning (mean=4.3, $SD=0.8$, and mean=3.0, $SD=0.7$, respectively) as well as during the procedure (mean=4.1, $SD=1.2$, and mean=0, $SD=0$). Since hallucinations occurred more frequently in the patients who did experience hallucinations, there was a higher probability of their occurring during the scanning procedure.

Since group differences in brain metabolic data might reflect the severity of any of the symptoms or neurocog-

nitive impairments rather than the presence or absence of hallucinations during the scan, correlations between these variables and hallucination scores during scanning were calculated. None of the symptom scale scores, the mean positive and negative symptom scores, or neurocognitive measures were significantly related to hallucination scores during the scanning procedure or before it. Thus, these hallucinatory events are independent of the other measures but might well be related to factors underlying severity of illness. Since these factors might be reflected in regional brain metabolism, we examined the relation of all symptom scores to regional brain metabolism.

One clear difference between groups is that they did or did not hallucinate during the FDG uptake period before the scan. Hallucinations occur intermittently, while the other symptoms are more constant.

Procedure

Informed consent, following a full explanation of all procedures employed in the study, was obtained from all subjects. An experienced psychiatric nurse cared for the subjects and inserted a number 18 angiocatheter into a vein of the forearm. Subjects were injected with FDG, 5 mCi, while lying on a comfortable stretcher. They were instructed to keep their eyes closed and were not spoken to. The only noise was due to the air handling system of the building. Warming the arm produced arterialized samples of venous blood that were taken from the arm opposite that used for FDG injection for the determination of plasma glucose and FDG concentrations. Scanning was started 45 minutes after FDG injection. Local rates of cerebral glucose metabolism were calculated according to the method of Brownell et al. (5). The procedures and methods have been more fully described elsewhere (3, 6).

The Schedule for Affective Disorders and Schizophrenia—Change Version (SADS-C) (7) was administered immediately before the glucose uptake period by the nurse so that ratings of positive and negative symptoms, initially obtained on admission, could be checked. Scales for the assessment of five negative symptoms (Scale for the Assessment of Negative Symptoms) and four positive symptoms (Scale for the Assessment of Positive Symptoms) were 6-point scales in which each level of intensity was defined in behavioral terms (8) (table 1). The ratings are based on interview data and on behavioral observations by staff and family members. The patients were well-known to the highly experienced research nurse (S.F.).

Immediately before being placed in the tomograph, patients were asked to report any auditory hallucinations they had during the uptake period for FDG. These reports were recorded and reviewed together with an experienced clinician (J.M.C.), and a consensus rating was made. The mean hallucination score for the hallucinating patients was 4.1 (SD=1.2). A rating of 3 describes the hallucination as vivid, occasional, and both-ersome; a rating of 4, as vivid and frequent.

Local Cerebral Glucose Metabolism

Regional distribution of FDG was measured with the McMaster PET, which has a spatial resolution of 8 mm (full width at half maximum) in the plane and 12 mm in the axial direction (9). It can therefore resolve voxels of less than 1 cm³. At least 10⁶ counts were collected, in 3 minutes, for each slice. The subject's head was held in a Perspex restraining device. Alignment in the left-to-right axis was ensured by inspection of a preliminary scan taken at the level of the thalamus. Typically, 16 slices of the brain (on a plane 5° to the orbitomeatal line) were obtained sequentially from the level of the hippocampal gyri up to the level of cortical vertex. Although each slice was 15 mm thick, it overlapped its predecessor by 10 mm. With this procedure, the slice with greatest volume of gray matter of interest for each subject can be identified and selected. For this study, three slices were first selected for analysis (figure 1). The lowest slice (midthalamic-midstriatal slice) contained the largest amount of temporal cortex, thalamic, and striatal tissue; auditory cortex is defined as segments 10 and 11 (figure 2). The procedure for dividing the cortex into segments is shown in figure 2. The middle slice (midcallosal slice) passed above the basal ganglia through the midportion of the dorsoventral extent of the corpus callosum. Language regions of the brain were approximately located by transposing brain stimulation maps onto the PET image, as described by us (3), and are shown in figures 1 and 2.

Data Analysis

In order to test the hypothesis that language areas of the brain are involved in auditory hallucinations, the groups of patients who did and did not hallucinate during FDG uptake were compared. A two-way analysis of variance (ANOVA) was used to examine group and laterality differences and their interactions in each region of interest, followed by *t* tests (two-tailed) for post hoc comparisons. Frontal and parietal relative metabolism was later examined by using the same methods.

RESULTS

The groups did not differ significantly in absolute whole brain glucose metabolic rate: the mean for patients who did experience hallucinations was 34.50 $\mu\text{mol}/100 \text{ g}/\text{min}$ (SD=10.10), and the mean for patients who did not experience hallucinations was 32.40 $\mu\text{mol}/100 \text{ g}/\text{min}$ (SD=6.70). There were no significant differences between the means of tomographic slices within or between groups.

Relative Regional Metabolism and Laterality

To test the hypothesis that language areas of the brain are involved in auditory hallucinations, groups were compared by two-way ANOVA (Group by Laterality)

FIGURE 2. Cortical Rim, Divided Into 36 Segments Each Spanning an Arc of 10°, Examined in 22 Schizophrenic Patients With and Without Auditory Hallucinations During PET Scan^a

^aThe borders were defined by an edge-detecting algorithm. In the low slice central structures are corpus striatum and, to the posterior, thalamus. Auditory cortex is defined as segments 10 and 11 and Wernicke's region as segments 9–13. In the middle slice no structures are visible in the center of the brain. Broca's region is defined as segments 6–8 in that slice (see text). In the high slice the cingulate gyrus is visible, as well as the rim of the cortex.

and by *t* tests in each region in the temporal and supramarginal areas and Broca's regions in frontal cortex (figure 1). Since the striatum has a role in language, it was also included in the analysis. The results show trends toward higher relative metabolism in the right hemisphere regions homologous for Broca's and lower relative metabolism in primary auditory areas and in the right superior temporal region, which includes part of auditory association cortex, in the patients who did experience hallucinations. For the right hemisphere homologue of Broca's, the mean relative metabolism in the patients who did experience hallucinations was 1.04 (SD=0.04), and the mean in patients who did not experience hallucinations was 1.03 (SD=0.05) ($t=1.77$, $df=20$, $p=0.09$). For the right auditory, the mean in patients who did experience hallucinations was 1.03 (SD=0.05), and the mean in patients who did not experience hallucinations was 1.07 (SD=0.05) ($t=1.82$, $df=20$, $p=0.08$). For the right superior temporal, the mean in patients who did experience hallucinations was 1.01 (SD=0.04), and the mean in patients who did not experience hallucinations was 1.05 (SD=0.04) ($t=1.91$, $df=20$, $p=0.07$).

The differences reach significance in the posterior half of the superior temporal gyrus, the mean of regions 9–14 on the left and 23–28 on the right (figure 2) ($F=6.59$, $df=1$, 20 , $p=0.02$), with the patients who did experience hallucinations having lower relative metabolism (mean=1.03, SD=0.02) than patients who did not experience hallucinations (mean=1.05, SD=0.02). When the left-handed patients were removed from the analysis, the posterior temporal values were significantly lower in the patients who did experience hallucinations

(mean=1.03, SD=0.02) than in the patients who did not (mean=1.05, SD=0.02) ($F=8.74$, $df=1$, 17 , $p=0.009$). The mean of right and left auditory regions was also significantly lower in the patients who did experience hallucinations than in those who did not (mean=1.01, SD=0.03, $N=9$, versus mean=1.05, SD=0.04, $N=10$) ($F=6.42$, $df=1$, 17 , $p=0.02$).

There was also a significant Group by Laterality interaction in the anterior temporal region ($F=4.57$, $df=1$, 20 , $p=0.05$). When the three left-handed patients were removed from this analysis, the interaction became nonsignificant. An interaction between group and laterality in the striatum was significant whether or not left-handers were deleted ($F=4.78$, $df=1$, 20 , $p=0.04$); in patients who did experience hallucinations, the mean left relative metabolism was 0.98 (SD=0.09) and the mean right was 0.98 (SD=0.09); in patients who did not experience hallucinations the mean left relative metabolism was 0.94 (SD=0.08) and the mean right was 0.98 (SD=0.05).

There were no significant differences between groups in relative metabolism in supramarginal, frontal, or parietal regions or in the anterior or posterior cingulate gyrus or thalamus, as depicted in figures 1 and 2.

Correlations Between Symptom Scores and Relative Regional Metabolism

Hallucination scores correlated with striatum ($r=0.68$, $N=12$, $p<0.01$, one-tailed, Pearson product-moment correlation), left striatum ($r=0.69$, $p<0.01$), right striatum ($r=0.64$, $p<0.02$), and anterior cingulate ($r=0.52$, $p<0.05$). Hallucination scores or other symptom

TABLE 2. Correlations Between Relative Metabolism in Selected Brain Regions in Schizophrenic Patients With and Without Auditory Hallucinations During PET Scan

Brain Region	Correlation (r)		Probability of Significant Difference Between Correlations (Fisher's exact test)

scores were not significantly related to any of the regions of interest.

Neuroleptic Effects

Nine patients were reexamined after 1–2 years of neuroleptic treatment. We calculated correlations between change over the 1–2 years in relative metabolism and change in symptom scores ($N=9$). The decrease in hallucination scores was significantly related to a decrease in high frontal values ($r=0.89$, $p<0.01$) and an increase in high right parietal values ($r=0.84$, $p<0.01$). Reduced hallucination scores were also correlated with a reduction in the frontal/parietal ratio ($r=0.89$, $p<0.01$). These changes may be reciprocal, since they are based on changes in the same tomographic slice. The metabolic data are ratio data and share the same denominator. The reduction in total positive symptom scores was associated with increased values in striatum ($r=0.90$, $p<0.01$).

Correlations between brain regions were significantly different in patients who did experience hallucinations than in those who did not in seven of 18 regions meas-

ured ($p<0.01$, Fisher's exact test) (table 2). Correlations in the patients who did experience hallucinations were not significantly different from those in the healthy control subjects ($N=30$). The pattern of regional correlations within hallucinating patients resembled that in healthy control subjects, while the pattern in nonhallucinating patients did not.

DISCUSSION

Relative metabolism in the posterior superior temporal regions of both hemispheres was significantly lower in patients who hallucinated compared to those who did not hallucinate during FDG uptake before scanning. Similarly, the auditory region on the right showed a trend in the same direction, as did the right hemisphere homologue for Broca's region. Right/left ratios in the anterior temporal and striatal regions were significantly lower in the hallucinatory state.

When left-handed subjects were removed from the analysis, the regional differences were greater and the left/right asymmetry differences were smaller. Since we

do not know whether the left-handed subjects had language represented in the right hemisphere, we cannot say which analysis is better.

The lack of convincing differences in other language regions is consistent with the findings of Buchsbaum et al. (10), who compared patients who did experience hallucinations with those who did not in their initial work on hypofrontality, and with our study of chronic, medicated hallucinating patients (3), whose indifference to hallucinatory experiences suggested to us that they were not attending to their voices. This lack of statistical power may also reflect the weakness of the stimulus: auditory hallucinations occurred intermittently during the 45-minute uptake period. When the data are compared with language stimulation studies in normal subjects (see following discussion), a stronger effect might be expected if the stimuli (hallucinations) occupied more of the uptake time. Studies with ^{15}O labeled water, whose half-life is 2 minutes, may make this possible.

We examined the data for possible confounding effects of differences between patients who did and did not experience hallucinations in symptom severity and cognitive impairment. The fact that neurocognitive deficits were more severe in the patients who did experience hallucinations than in those who did not supports the data on symptoms suggesting that the patients who did experience hallucinations were more severely ill in both domains. These domains appear to be separate, since we have not found any significant relations between symptom scores and neurocognitive scores in our studies, even when these patients were included in a larger sample ($N=27$) (11). Cognitive test scores are not significantly related to glucose metabolism in language regions. Rather, scores on tests of registration of information covary positively with the level of frontal metabolism (11).

None of the symptoms other than hallucinations was related to glucose metabolism in language regions. Furthermore, none of the other symptom scores was significantly related to hallucination scores.

In the striatal and cingulate regions relative metabolism was positively and significantly correlated with hallucination scores in the patients who did experience hallucinations. In our previous study of chronic hallucinating patients, we also observed that hallucination scores correlated positively and significantly with anterior cingulate relative metabolism (3). In that chronic, neuroleptic-treated patient group, however, the striatal metabolism was not statistically implicated—a finding that can be understood in that neuroleptics significantly alter striatal relative metabolism (12). These correlations are in contrast with the report of Mathew et al. (13) of negative correlations of hallucination scores on the Brief Psychiatric Rating Scale with cerebral blood flow (CBF) in left parietal, left temporal, right temporoparietal, and right occipital cortices.

We failed to replicate differences between the groups in correlations between certain language regions that we reported in chronic medicated schizophrenic sub-

jects (3). Although seven of 18 correlations between language regions differentiated patients who did experience hallucinations from those who did not, the analysis of correlations between regions in a new control group ($N=30$) demonstrated no difference between patients who did experience hallucinations and control subjects. Thus, in this population, correlational analysis did not reveal a pattern characteristic of the hallucinatory process.

Prior substance abuse was an important factor in the chronic patient study in that substance abuse ratings correlated with hallucination scores ($r=0.53$, $p<0.01$) and with left anterior temporal metabolism ($r=0.59$, $p<0.01$). Substance abuse was not significantly related to hallucination scores or regional brain metabolism in the present study. It is possible that substance abuse aggravates auditory hallucinations through different pathways than those which usually mediate auditory hallucinations in schizophrenia.

Musalek et al. (14) have recently reported CBF changes during auditory hallucinations. CBF was measured by single photon emission computerized tomography in neuroleptic-treated patients with chronic auditory hallucinations that had resisted treatment. Hallucinations were associated with significantly increased blood flow in the anterior basal ganglia and medial temporal areas and relative frontal hypoactivity. In that study, p was set at 0.05 despite multiple comparisons and a study group of 17 subjects. If we had allowed this statistical criterion, our results might have been similar. Our data are, in general, consistent in implicating basal ganglia and temporal regions but not frontal hypoactivity.

A role for the striatum in auditory hallucinations is strongly supported by our data. Hallucination scores correlated positively and significantly with striatal relative metabolism. We have previously reported that neuroleptic treatment significantly reduces hallucination scores while significantly increasing striatal metabolism (15), and we now have shown that these two processes are related to a statistically significant degree. Change in frontal and parietal regions are also related to improvement in hallucinations, but these regions were not implicated at the time the hallucinations occurred. Nevertheless, it is possible that the significant increase in parietal metabolism and the decrease in frontal metabolism, which was correlated with a decrease in hallucination scores, could reflect a shift in attention from internal to external events.

Our studies, discussed earlier in this paper, and the evidence that auditory hallucinations can be stopped by immobilizing the larynx by opening the mouth wide (2) and by speaking or writing provide strong evidence that language mechanisms are involved in auditory hallucinations. How do auditory hallucinations differ from normal language?

Studies in normal subjects have presented language stimuli repeatedly and throughout the period of radiotracer uptake before PET scanning. Listening to monosyllabic words and phonemes (16) and to a com-

plex story (17) activates left perisylvian regions. Tasks that require semantic interpretation activate left inferior frontal (including Broca's) and anterior cingulate regions. Complex tasks also involve superior prefrontal activity (18, 19). This is not the pattern during auditory hallucinations, however.

Wernicke's region and auditory cortex showed significantly lower relative metabolism in hallucinating patients, while the right hemisphere homologue of Broca's region showed a nonsignificant trend toward activation. This same pattern in Wernicke's region has recently been observed in a PET CBF ^{15}O study by Frith et al. (20). Subjects required to speak words aloud showed suppression of Wernicke's regional blood flow (and activation in left prefrontal cortex). Thus, the pattern we observed is similar in part to that seen in subjects speaking and listening to their own voices. This is consistent with electrocortical observations in monkeys (21). Auditory cortex was activated in animals while they listened to a tape recording of their own voices but not while they vocalized. The failure to activate left prefrontal cortex including Broca's region may reflect the lack of intentionality characteristic of hallucinated language.

In addition, the striatum is implicated. While PET studies of language in normal subjects (16–18) do not mention the striatum, striatal lesions can contribute to aphasia (22, 23) and indirectly disrupt cortical processes involved in perceptual organization of auditory stimulation (24). We suggest that future studies determine whether auditory hallucinations involve the striatum to a greater extent than do normal listening and speaking.

An abnormality in the striatum might lead to hallucinations, since it is a repository of overlearned behaviors and is known to be involved in intermittent involuntary movements. Hallucination can be seen as involuntary thought and language events. Furthermore, PET studies suggest that the striatum may be the principal site of action for neuroleptics that usually ameliorate hallucinations (12).

In addition, patients who experience hallucinations are characterized by failure to discriminate the location of sounds, which may underlie the failure of reality discrimination with respect to the location of the speaker's voice (25). We may not have adequately measured metabolism in the right inferior parietal region, which subserves that locating function (26). Furthermore, the anterior cingulate is required for discriminating intended vocalizations from other auditory stimuli (27) and appears to have a role in auditory hallucinations in the present study and our previous study (3) in that the intensity of hallucinations and relative metabolism in the anterior cingulate are positively and significantly correlated.

In summary, comparison of our data on hallucinating patients with data on regional brain metabolism in normal language suggests that future studies compare auditory hallucinations and language task involvement of striatum, anterior cingulate, and parietal cortices and Broca's and Wernicke's regions. A picture of the hallu-

inating brain may thus be constructed and errors in the processes of generating and listening to language may be identified.

Are Males More Likely Than Females to Develop Schizophrenia?

William G. Iacono, Ph.D., and Morton Beiser, M.D.

Objective: This study was undertaken to determine whether the incidence of schizophrenia is equivalent for males and females. **Method:** An attempt was made to identify every first-episode case of psychosis in a large Canadian city over a period of 2½ years. A comprehensive referral network was established that included hospital and community settings where psychotic persons might appear. More than 300 potential subjects were identified, 175 of whom underwent a structured psychiatric interview and were assigned diagnoses according to five different diagnostic systems. **Results:** The incidence of schizophrenia was two to three times higher among males than among females. Even though the use of different diagnostic systems yielded slightly different risk rates, the elevated risk for males remained consistent. There were no differences between the sexes in the incidence of affective psychosis. In comparison with schizophrenia, the incidence rates for mood disorders with psychotic features were sometimes lower and sometimes higher, depending on the diagnostic system used. **Conclusions:** The findings, coupled with reports in the past 10 years from other investigators, challenge the conventional belief that the incidence of schizophrenia is the same for the two sexes.

(Am J Psychiatry 1992; 149:1070-1074)

Knowledge about the sex distribution of psychosis among adults is important for several reasons. Because males and females differ in biology, rate of maturation, social status, and duration and types of experiences encountered, differences in the proportion of males and females afflicted with a disorder can suggest etiological clues (1). Moreover, males are more likely than females to develop psychoses in childhood. Whether this pattern continues with increasing age, thus suggesting that males are more vulnerable to severe psychopathology even in adulthood, is also of great interest.

Although authorities have long agreed that the prevalence and incidence of schizophrenia are the same for both sexes (2, 3), surveys in the past 10 years have provided inconsistent results. While studies in Asia (4), Europe (5-8), and North America (9, 10) have suggested an excess of schizophrenia among males, the Na-

tional Institute of Mental Health (NIMH)-sponsored Epidemiological Catchment Area (ECA) survey suggested that among noninstitutionalized populations, rates of schizophrenia are higher among women than among men (11). The World Health Organization (WHO) study of the incidence of schizophrenia (12) demonstrated no consistent pattern of male-female differences across sites. Studies of mood disorder have been more consistent in suggesting that men and women have an equal risk of developing bipolar disorder but that women have higher rates of major depressive disorder (13). However, studies of major depressive disorder have not differentiated between the relatively small percentage of individuals who have affective disorder with psychotic features and those who have affective disorder in general.

This report examines sex ratios in a broadly based sample of persons suffering a first episode of psychosis. First-episode subjects are particularly well suited for the study of sex differences. Studies that examine chronic patients risk confounding estimates of the sex distribution with sex differences in the course of psychotic illness, which is known to be more severe in schizophrenic men (14).

To avoid potential bias associated with reliance on institutionalized patients from a single setting, subjects were recruited from multiple sources both within and outside the traditional mental health care system. The project goal was to come as close as possible to obtaining a sample of all residents in a major Canadian coastal city who were experiencing psychotic symptoms

for the first time in their lives. Since diagnostic criteria might influence estimates of relative risk, we compared male and female incidence rates (based on the number of new cases identified each year) using different diagnostic systems. To our knowledge the present study is the first to explore sex distributions in a large, community-based, diagnostically heterogeneous sample of first-episode psychotic patients.

METHOD

Subjects were recruited in Vancouver, B.C., Canada, from a metropolitan catchment area of approximately 480,000 persons. The referral network included all psychiatric hospitals and psychiatric services of general hospitals, university and college counseling services, community mental health centers, psychiatrists in private practice, private counseling services, employment and immigration counseling services, and a random sample of one-sixth of all general practitioners in Vancouver. About 18% of the referrals were from other than inpatient hospital services, including 9% from community mental health centers, 7% from private practice clinicians and community agencies, and 2% from hospital outpatient services. Over a period of 2½ years beginning in 1982, we identified a total of 318 potential subjects for our study. Of these, 31 terminated contact with their referral source or disappeared before we could contact them, and 94 refused to be interviewed. Although these 125 nonparticipants were not entered into our study, we were able to ascertain their ages, sex, and the diagnoses assigned by the referral sources. An additional 18 subjects agreed to participate but were dropped when they were found not to be psychotic or to be ineligible because they had experienced a previous episode of psychosis. Thus, 175 individuals, all of whom were experiencing their first lifetime episode of psychosis, gave informed consent to participate in the study.

To cast as wide a referral net as possible, we supplied our referral agencies with a broad definition of potential cases, including persons 1) who were currently psychotic (i.e., experiencing hallucinations or delusions, displaying grossly disorganized behavior, showing marked thought and speech disorder, or having two of the following symptoms: marked loss of drive, social withdrawal, severe excitement, overwhelming anxiety or fear, and gross self-neglect) and 2) who had not been treated before the present episode with antipsychotic, antimanic, or antidepressant drugs. Other inclusion and exclusion criteria required 1) that the subjects had lived in the Vancouver metropolitan area for at least 6 months, 2) that they were between 15 and 54 years of age, and 3) that they did not have an organic cerebral illness, severe mental retardation, a chronic physical disorder, or chemical dependence. A psychiatrist or clinical psychologist examined all potential subjects, including doubtful and borderline cases, initially recruited for the study using a structured psychiatric in-

terview (the Present State Examination) (15). Information from the psychiatric interview, reviews of clinical charts, and interviews with family members and friends was brought to case conferences attended by the project staff, including at least two experienced diagnosticians; this process resulted in a "best estimate" diagnosis (16) for each subject.

We used five different diagnostic systems, which varied in the breadth of their definition of schizophrenia, to classify participants: *DSM-III*, *ICD-9*, the Research Diagnostic Criteria (RDC) (17), the Feighner et al. criteria (18), and the 12-point flexible system of Carpenter et al. (19). With the exception of *ICD-9*, each of these systems has an explicit set of criteria for making diagnoses. To adapt the fairly loose *ICD-9* psychotic disorder categories for research purposes, the project clinicians used a checklist of symptoms and diagnostic criteria derived from the clinical constructs described in the *ICD-9* manual.

To ensure that subjects received the most accurate diagnoses possible, all symptoms and diagnostic criteria associated with the psychotic disorders described in each diagnostic system were reviewed for each patient to determine whether each symptom was present or absent. Then the diagnostic algorithms specified for each system (or the descriptive guidelines presented in *ICD-9*) were strictly followed to arrive at a diagnosis. Only subjects who satisfied the criteria for an active psychotic disorder in at least one diagnostic system were retained for study.

RESULTS

To determine whether an excess of patients of either sex was present in a category or group, we used chi-square tests to compare observed frequencies against the a priori expectation that the sexes would be equally represented. Among the 175 participants, who ranged in age from 16 to 50 years (mean=25.0 years, SD=7.8, for males; mean=25.7 years, SD=8.9, for females), 68% (N=119) were male, a proportion that deviated significantly from the expected rate of 50% (goodness-of-fit $\chi^2=22.68$, df=1, $p<0.001$). The percentage of male participants by diagnostic category within each diagnostic system is presented in table 1. The diagnostic systems are ordered such that the one with the broadest definition of schizophrenia (*ICD-9*) is on the far left. As table 1 shows, the broadest categorization resulted in a total rate of schizophrenia (114 cases) that was almost three times higher than that found when the most stringent diagnostic approach was used (41 cases according to the criteria of Feighner et al.). Regardless of the diagnostic system used, about three-fourths of all cases of schizophrenia involved males. Subjects with *DSM-III* schizophreniform disorder and RDC schizoaffective disorder were also disproportionately male.

The number of patients with mood disorders also varied depending on the diagnostic system used. *DSM-III* identified the largest number and the criteria of

Feighner et al. the smallest number. Patients with psychotic mood disorders, however, were not significantly more likely to be of one sex than the other. Regardless of diagnostic approach, the number of subjects with a first episode of manic psychosis approximately equaled the number with a first episode of depression.

Our data make it possible to compare the frequency with which a first episode of psychosis was likely to be

mood related (depression or mania) or fall within the schizophrenia spectrum (schizophrenia, schizophreniform disorder, or schizoaffective disorder). If we assume that these two types of psychosis are equally probable, the results show that schizophrenia-spectrum psychoses predominated according to ICD-9 (goodness-of-fit $\chi^2 = 24.05$, $df = 1$, $p < 0.001$) and the RDC ($\chi^2 = 32.69$, $df = 1$, $p < 0.001$) but that the two classes of psychosis occurred with equal frequency according to the DSM-III and Feighner et al. criteria.

Examining the distribution of the sexes with the expectation that their numbers should be equal is open to potential error. First, this expectation, largely derived from prevalence data, may not pertain to incidence. Second, it fails to take into account possible differences in the numbers of males and females at risk in the general population. The population at risk—that is, persons between the ages of 15 and 54—was determined from Canadian census figures and consisted of 241,217 males and 239,185 females. The number of cases of disorder per year was calculated by dividing the number of cases by the period (in years) over which cases were recruited. The result was then divided by the number of individuals at risk to yield an estimate of 1-year incidence per 100,000 population. Incidence data, along with the male-female risk ratio, for the subjects with schizophrenia, schizophrenia-related psychoses (schizophreniform and schizoaffective disorder), and mood disorders are presented in table 2. These data are consistent with those in table 1 in suggesting that regardless of diagnostic approach, the incidence of schizophrenia is greater in males than in females. By contrast, there were no differences between the sexes in the incidence of affective psychosis.

It is unlikely that the persons who refused to participate or did not participate can account for the findings. Comparing participants with nonparticipants on age, sex, and diagnosis revealed few differences between the groups. The nonparticipants were about the same age as the participants (range=16–49 years; mean=25.1 years, $SD = 8.3$, for males; mean=27.1 years, $SD = 9.0$, for females); and although the participants were slightly

less likely to be male (58%), the total sample of participants and nonparticipants was 64% male, a proportion that still differs significantly from the expected 50% ($\chi^2=21.87$, $df=1$, $p<0.001$). The data also indicated that there was little difference between the diagnoses assigned to participants and nonparticipants by the referring agencies, all of which were using *DSM-III* or *ICD-9* at the time this study was conducted.

The incidence (per 100,000 population) of schizophrenia-related psychoses among nonparticipants was 8.95 for males and 5.30 for females. Although these referral-source diagnoses were probably less trustworthy than those made by the project diagnosticians, adding these cases to those of the project participants diagnosed according to narrow and broad definitions of schizophrenia provides an opportunity for a rough examination of risk ratios in the entire sample of possibly schizophrenic persons. When the nonparticipants with schizophrenia-spectrum psychoses are added to the participants with *DSM-III* diagnoses, the incidence figures are 15.76 and 7.26 for males and females, respectively, and the risk ratio is 2.17 (goodness-of-fit $\chi^2=16.41$, $df=1$, $p<0.001$). When these nonparticipants are added to the participants with the *ICD-9* diagnosis of schizophrenia, the corresponding figures are 19.85, 9.42, and 2.11 (goodness-of-fit $\chi^2=19.44$, $df=1$, $p<0.001$). Hence, even when the nonparticipants are taken into account, males still exhibit a higher incidence of schizophrenia-spectrum diagnoses than females.

DISCUSSION

The incidence of schizophrenia reported in this study is similar to that found in other surveys (20), including the WHO incidence study (12), the design of which was similar to that of our investigation and which also used subjects between the ages of 15 and 54. Our results demonstrate a higher incidence of schizophrenia and related disorders among males, but no differences between the sexes in the incidence of psychotic affective disorders. Our results for schizophrenia are consistent with several reports (all since 1984) indicating a higher incidence of schizophrenia among men than among women. NiNullain et al. (7), in an investigation of first admissions in three Irish counties, found that depending on the breadth of the criteria used to diagnose schizophrenia, 59%–68% of the subjects were male. These investigators also reported data indicating that on the basis of 1983 first-admission statistics for all of Ireland, the male-female risk ratio for schizophrenia was 1.50. Bland's report (9) of the rate of first admissions for schizophrenia in Canada indicated a risk ratio of 1.41. Even higher figures were found in Nottingham, England, for schizophrenia diagnosed according to *DSM-III* (risk ratio=2.43) (5) and in Denmark (risk ratio=2.29) (6). In their study of the incidence of schizophrenia in four Canadian provinces, Wattie and Kedward (10) found that 60% of their subjects were male. Stromgren (8) noted that despite a decrease in the over-

all incidence of schizophrenia from 1970 to 1984 in Denmark, for each calendar year the number of males succumbing to a first episode of schizophrenia was consistently higher than the number of females. Finally, in the WHO eight-center study of the incidence of schizophrenia (12), when paranoid and certain reactive states were excluded from the schizophrenia spectrum, six of the eight sites reported an excess of males. Only Moscow and an urban setting in India deviated from this pattern. Taken together with our findings, all of these reports challenge the conventional belief that the incidence of schizophrenia is equal for both sexes.

One possible explanation for these observations of an excess of males with schizophrenia stems from the hypothesis that the criteria for the diagnosis of schizophrenia have been narrowed. This phenomenon could lead to more men being diagnosed as schizophrenic and more women—since they are more likely to have affective features (13)—being diagnosed as having mood disorders (21). However, we found that differences between the sexes in incidence were the same regardless of the breadth or narrowness of the diagnostic criteria. Other investigations that have examined the incidence of schizophrenia as a function of breadth of the diagnostic criteria (5, 7) have also failed to find that narrowing the criteria leads to an excess of males with the diagnosis.

The excess of male schizophrenic subjects in our sample might have resulted from our elimination of females with this disorder who failed to meet our eligibility criteria. Compared with men, women with schizophrenia tend to be diagnosed at later ages (13, 22). Since women with psychiatric disorders are more likely than men to seek help from family physicians (23, 24), it is possible that some females who were potentially eligible for our project had received treatment at some point in their lives before they came to the attention of the mental health system and thus were disqualified from our study. This seems unlikely, however, because the patients who were referred to but did not participate in the study were not screened for prior treatment and yet were still predominantly male.

Other investigations, notably the WHO study of incidence (12), have used similar exclusion criteria. However, since these studies did not report data on noneligibility or refusal rates, comparisons are impossible. We were able to identify virtually all individuals with a first episode of psychosis, whether they participated in the study or not, who were involved with the inpatient or outpatient mental health care system or who appeared in other service settings in our catchment area. While it is possible that there were private practice physicians treating first-episode female psychotic patients who did not require hospitalization and who were not referred to our study, we have no reason to suspect that our data would differ from those of other investigators for this reason, since such cases would be unavailable at any site. Nevertheless, because of limitations to the thoroughness with which we could identify cases, studies such as ours leave open the possibility that women

with milder, less disruptive schizophrenia were missed. Because of this possibility, our report is better able to provide grounds for raising the question posed in its title than to answer the question definitively.

If our findings are correct, they may have implications for understanding the etiology of schizophrenia. If males are more susceptible to schizophrenia, this fact, coupled with their tendency to show an earlier age at onset (22) and a more debilitating course (14), suggests that males may be more biologically vulnerable and less able to adapt to psychosis than females. The sexes differ in their anatomy and physiology, processes of biological maturation, social status, occupational attainment, and duration and types of psychosocial experiences encountered. Examining variables related to such factors may provide valuable clues to understanding how schizophrenia develops.

Although data on the incidence of mood disorders exist, to the best of our knowledge, our study is the first to focus on first-episode cases with manifest psychotic features. Our results demonstrate that these disorders are distributed about equally across the sexes, a finding that does not depend on the breadth of the criteria used to diagnose these disorders. However, the diagnostic criteria do seem to influence the likelihood of receiving a mood- or schizophrenia-related diagnosis. The two systems with the broadest definitions of schizophrenia that also provided for the diagnosis of mood psychosis (ICD-9, RDC) identified significantly more schizophrenia-related disorders than mood disorders. With the DSM-III and Feighner systems, there was only a slight, nonsignificant trend for schizophrenia-related disorders to outnumber mood disorders.

Painful Sensory Symptoms in Neuroleptic-Induced Extrapyramidal Syndromes

Paolo Decina, M.D., Sukdeb Mukherjee, M.D.,
Giovanni Caracci, M.D., and Kay Harrison, R.N.

Objective: The authors tested the hypothesis that neuroleptic-induced extrapyramidal syndromes are associated with painful sensations objectively conforming to the characteristics of primary sensory symptoms as reported in idiopathic and postencephalitic parkinsonism. **Method:** The frequency of subjective painful sensory symptoms and their relation to neuroleptic-induced extrapyramidal syndromes were examined in a consecutive series of 107 psychiatric patients newly admitted to acute care units at a teaching hospital. Patients without illnesses or conditions likely to be associated with pain were included in the study if they had a diagnosis other than organic mental syndromes and were receiving psychotropic medications as prescribed by their treating physicians. Structured interviews with a modified version of the McGill Pain Questionnaire to assess sensory complaints and neurological examinations for neuroleptic-induced extrapyramidal syndromes (parkinsonism and akathisia) were conducted independently by two raters blind to each other's findings and patients' medication status. **Results:** Fourteen (23%) of 60 patients receiving neuroleptics reported experiences of spontaneous pain subjectively attributed to pharmacological treatment, compared with only one (2%) of 47 patients receiving psychotropic medications other than neuroleptics. There was no difference between these two groups in subjective complaints of paresthesia (8% versus 9%). Twelve (55%) of the 22 patients with neuroleptic-induced extrapyramidal syndromes reported pain, compared with only two (5%) of the 38 patients who received neuroleptics but did not experience extrapyramidal syndromes. **Conclusions:** Although consonant with the study hypothesis, these results should be regarded as preliminary and interpreted conservatively in the light of the methodological limitations of the study.

(Am J Psychiatry 1992; 149:1075-1080)

It is well established that a substantial proportion (about 40%) of patients suffering from postencephalitic or idiopathic parkinsonism experience distressing and ill-defined sensations that cannot be attributed directly to disorders of the musculoskeletal system, antiparkinsonian medications, peripheral neuropathy, or gross pathology of sensory pathways of the brain (1-5). These are commonly referred to as primary sensory symptoms, to distinguish them from sensory manifestations that may be attributed to disorders of the musculoskeletal system and therefore considered secondary. Subjective accounts of these disagreeable sensations vary widely, and some patients may have unusual

difficulties in describing them, perhaps because of a lack of comparable sensations associated with common diseases and life experiences (4). Nevertheless, primary sensory phenomena in parkinsonism have been readily classified into paresthesias and pain, the former including sensations of burning, coldness, tingling, and numbness and the latter comprising poorly localized painful sensations without thermal or anesthetic characteristics and not associated with increased muscle contraction or affected by movements or pressure (4). The pathophysiology of primary sensory symptoms in parkinsonism remains unknown, although it is believed that they result from central dopaminergic deficiency in the basal ganglia or other systems as a consequence of the disease process (2, 4, 6).

Parkinsonism and akathisia often occur in patients receiving neuroleptic drugs and are believed to be caused, at least in part, by the blockade of postsynaptic dopamine receptors (7). These neuroleptic-induced extrapyramidal syndromes share phenomenological, pharmacological, and biochemical characteristics with both idiopathic and postencephalitic parkinsonism (8, 9). In

Presented in part at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. addition, there is evidence that at least some patients with neuroleptic-induced parkinsonism, particularly those who are elderly, may have underlying Parkinson's disease (10, 11). Thus, it is conceivable that neuroleptic-induced extrapyramidal syndromes may also be associated with primary sensory symptoms. The aim of this study was to test this hypothesis, first by examining the frequency of primary sensory symptoms in patients receiving neuroleptics compared with patients receiving psychoactive drugs other than neuroleptics, and then by contrasting the frequency of these sensory symptoms in patients with neuroleptic-induced extrapyramidal syndromes and patients without neuroleptic-induced extrapyramidal syndromes.

METHOD

The study group comprised 107 consecutive voluntary psychiatric inpatients recruited from five acute care units at an urban teaching hospital. Patients were included in the study if they had been newly admitted, had a psychiatric diagnosis other than organic mental syndrome, and were currently receiving psychotropic medications as prescribed by their treating physicians. Patients with a history of alcohol or substance abuse, neurological illnesses, musculoskeletal conditions (arthritis, muscle spasms), diabetes, and vascular disease and those concurrently being treated with ECT were excluded.

At the time of assessment, 60 patients were receiving neuroleptics, and 47 were receiving psychotropic drugs other than neuroleptics. In the patients receiving neuroleptics, haloperidol and trifluoperazine were the most frequently prescribed drugs, each compound accounting for about 30% of the patients. Chlorpromazine was administered to about 20% of patients, and the remaining patients received several other neuroleptics. The mean length of neuroleptic treatment during the index episode was 12 weeks ($SD=6.5$). Neuroleptic doses in chlorpromazine equivalents (12) ranged from 20 mg/day to 1660 mg/day, with a mean of 806 mg/day ($SD=461$). For the purpose of this study, chlorpromazine and thioridazine were considered low-potency neuroleptics and all other neuroleptics were classified as high potency. Anticholinergic drugs, usually benztropine mesylate, were used in 23 (38%) of the patients who received neuroleptics. Twenty (33%) of the 60 patients received combination treatment with lithium salts, antidepressants, or both. In the group of patients treated with psychotropic medication other than neuroleptics, 37 (79%) of the patients were receiving antidepressants, 15 (32%) lithium salts, five (11%) anticonvulsants, 12 (26%) benzodiazepines, and 22 (47%) a combination of these.

All patients were examined within the first 2 weeks of admission. One rater conducted structured interviews regarding sensory complaints subjectively attributed to the pharmacological treatment, and another rater examined patients for signs of parkinsonism and

akathisia. The two raters were blind to each other's findings and the medication status of patients. The structured interview regarding sensory complaints used a modified version of the McGill Pain Questionnaire (13; modified questionnaire available on request from P.D.). The McGill Pain Questionnaire is a structured interview that assesses the clinical features of painful states as well as the psychosocial context of subjects complaining of pain. For the purpose of this study, only the painful sensations specifically related by patients to the current pharmacological treatment were considered, and the interview was limited to those sections pertaining to the description of pain. In these sections, patients are asked to select from lists those words or subgroups of similar words best describing the frequency (e.g., continuous, steady, constant versus brief, momentary, transient), type (e.g., hot, burning, scalding versus cool, cold, freezing), and severity (on a 5-point scale on which mild=1 and 5=excruciating) of the painful sensations and to indicate with the help of body maps the localization of the pain, further specifying whether the sensations referred to the surface (i.e., skin) or inside the body (e.g., joint, muscle, bone). The section pertaining to the description of type of painful states was modified so that single words rather than groups of similar words were presented to the patients (e.g., burning rather than hot, burning, scalding). The questionnaire was also modified to include direct questions about complaints of heaviness and stiffness and about the possible coexistence of dystonic reactions with painful states. A similar revision of the McGill Pain Questionnaire was previously used in a study of pain in Parkinson's disease (1), and its clinical relevance for categorizing painful states in this condition has been demonstrated.

Subjective sensory complaints of heaviness and stiffness that likely were a result of rigidity or bradykinesia, or those associated with acute dystonic reactions, were not considered primary sensory symptoms. Primary sensory symptoms were recorded as either pain or paresthesias. In accord with neurological convention (1-4), burning sensations were considered paresthesias rather than pain. Four motor signs of parkinsonism (bradykinesia, rigidity, tremor, and postural instability) were rated on a standard 5-point scale (14) on which 0=absence of abnormal signs and 4=severe impairment, and the criterion for diagnosis of parkinsonism was a mean score of 1 on this scale. A combination of awareness of restlessness with characteristic restless movements such as rocking from foot to foot when standing defined akathisia (15).

Because of significant skewness in the distributions of age, pain intensity, and items representing parkinsonism, the data were analyzed by using nonparametric statistics. Specifically, bivariate comparisons were examined by using Spearman rank correlation coefficients, and between-group comparisons were examined by using Mann-Whitney tests. All values were corrected for ties. Chi-square tests with continuity correction were used to compare distributions of dichotomous

variables and diagnostic categories. Two-tailed significance values were used throughout.

RESULTS

Patients Receiving Neuroleptics Versus Those Receiving Other Medications

The neuroleptic-treated group included 26 men and 34 women; the patients treated with medications other than neuroleptics included 19 men and 28 women ($\chi^2=0.01$, $df=1$, $p=0.92$). The mean age of the patients receiving neuroleptics was 31.4 years ($SD=10.1$); that of the patients treated with other medications was 35.5 years ($SD=12.2$) (Mann-Whitney $U=1177$, $p=0.14$). The diagnoses of the two groups of patients are presented in table 1. The two groups were demographically similar but differed significantly in their diagnostic composition. Not unexpectedly, more of the patients receiving neuroleptics had psychotic conditions, such as schizophrenic disorders and psychotic mood disorders, than did the patients receiving other medications.

Fourteen (23%) of the 60 patients receiving neuroleptics complained of pain, in contrast to only one (2%) of the 47 patients treated with nonneuroleptic medications ($\chi^2=8.2$, $df=1$, $p<0.005$). There was no difference between the groups in subjective complaints of paresthesias: five (8%) of the patients receiving neuroleptics versus four (9%) of the patients receiving other medications ($\chi^2=0.10$, $df=1$, $p=0.75$). Among the patients receiving neuroleptics, the pain was described as intermittent by 10 of the 14 subjects, and aching was the most common type of complaint ($N=12$). Twelve patients localized their pain to the four limbs, and five to the back; none localized their pain to the head or ventral torso. Depth localization was defined as poorly localized by 11 patients.

Patients Receiving Neuroleptics Who Did Versus Those Who Did Not Have Neuroleptic-Induced Extrapyrimal Syndrome

Twenty-two (37%) of the 60 patients receiving neuroleptics met study criteria for neuroleptic-induced extra-

pyramidal syndromes. Of this group, 15 presented with parkinsonism, four with akathisia, and three with both. Demographic, clinical, and treatment characteristics of these patients did not significantly differ from those of patients classified as not having neuroleptic-induced extrapyramidal syndromes (table 2). Significantly more of the patients with neuroleptic-induced extrapyramidal syndromes complained of pain (table 2). In all 60 patients receiving neuroleptics, the reported intensity of pain was significantly correlated with the parkinsonism

severity score ($r=0.31$, $p<0.02$), and the pain intensity score was significantly higher among the patients with than those without neuroleptic-induced extrapyramidal syndromes (table 2).

The presence of pain was not related to sex, current age, neuroleptic dose, neuroleptic potency (high versus low), or anticholinergic drug use (table 3). When patients with akathisia alone were excluded from the analysis, subjective complaints of pain were noted in nine (50%) of the 18 patients with parkinsonism, in contrast to two (5%) of the 38 patients without parkinsonism ($\chi^2=12.8$, df=1, $p<0.001$). When patients with parkinsonism alone were excluded, subjective pain was noted in three (43%) of the seven patients with akathisia and in two (5%) of the 38 patients without akathisia ($\chi^2=5.1$, df=1, $p<0.05$). A forward stepwise regression analysis was conducted to determine which dimensions of neuroleptic-induced extrapyramidal syndromes (akathisia, bradykinesia, postural imbalance, rigidity of motor joints, and tremor) uniquely predicted the intensity of pain. Tremor ($F=7.1$, df=1, 58, $R^2=0.09$, $p<0.01$) and postural imbalance ($F=4.2$, df=1, 57, $R^2=0.06$, cumulative $R^2=0.15$, $p<0.05$) had significant predictive value, whereas associations were not statistically significant for the other variables ($F<1.5$ for all).

DISCUSSION

The main findings of this study were 1) patients receiving acute neuroleptic treatment exhibited more complaints of pain attributed directly to the medication than patients receiving psychotropic agents other than neuroleptics and 2) among the neuroleptic-treated group, complaints of pain were more frequent in patients with parkinsonism, akathisia, or both. The interpretation of these findings must be very cautious because the study is preliminary and has two major methodological limitations. First, data on complaints of pain were gathered in single interviews with a questionnaire that has not been standardized in psychiatric populations. Thus, the reliability of the findings is open to question. Undoubtedly, the absence of reliability data concerning the McGill Pain Questionnaire poses a major threat to the validity of the study and warns against any definitive interpretation of the results. Second, the cross-sectional design of the study leaves unanswered the question of whether pain is a direct adverse effect of neuroleptic treatment. Clearly, a prospective, longitudinal study in which complaints of pain are reliably measured before and during exposure to neuroleptics is more likely to adequately address this important question. The limitations notwithstanding, several clinically relevant observations were made.

The pain was usually described as a poorly localized, intermittent, aching sensation involving all four limbs symmetrically and sparing the head and ventral torso. This description of pain closely resembles that reported in the neurological literature on parkinsonism. Among patients receiving neuroleptics the intensity of reported

pain was significantly correlated with the severity of parkinsonism, and in univariate tests all components of the parkinsonian syndrome were rated higher in patients with pain than in those without pain. A stepwise regression analysis showed the relation between parkinsonism and pain to be mediated by tremor and postural balance rather than motor rigidity and bradykinesia. However, tremor, motor rigidity, and bradykinesia were highly intercorrelated, and chance may have emphasized the effect of one over the others. The finding could also have been influenced by our exclusion from consideration of complaints of heaviness and stiffness, which a priori were presumed to be secondary to rigidity and bradykinesia. By contrast, there was no relation between reported pain and akathisia in either univariate or multivariate analyses. Neither the presence nor the intensity of reported pain was related to age, sex, dose or potency of the neuroleptic, or adjunctive use of anticholinergic medications. In addition, reports of pain were almost equally distributed among psychiatric diagnoses, suggesting that patients did not report pain as a consequence of psychosis. However, the small number of patients (N=8) in the nonpsychotic group suggests caution in interpreting this finding, and we cannot rule out the possibility that at least some patients may have reported pain as a result of delusional or hallucinatory experiences.

To our knowledge, there have been no previous studies specifically examining sensory complaints associated with neuroleptic treatment. The report by Sigwald and Solignac (16) is the only notable exception to the general neglect of this issue. In a survey of sensory symptoms in 213 patients with parkinsonism, they commented on the similarities between the disagreeable or painful manifestations of Parkinson's disease and those associated with neuroleptic therapy. It is not entirely clear why there has been no follow-through on these original observations. In their evaluation of extrapyramidal side effects, patients and psychiatrists alike appear to have placed more clinical emphasis on the subjective emotional states engendered by neuroleptics than on sensory phenomena. If primary sensory phenomena associated with neuroleptics are mostly limited to pain, as the results of our study indicate, the fact that pain comprises both sensory and affective dimensions (17) and the difficulties in verbalizing adequately its sensory component may at least in part account for the lack of appreciation of sensory symptoms in the psychiatric literature.

Very soon after the introduction of neuroleptics into psychiatry, it was realized that "all the side effects of neuroleptics had already been described between 1920 and 1935 as a sequela of [Von Economo] encephalitis" (18). The spectrum of symptoms included specific mental states associated with certain motor disturbances, that is, bradyphrenia associated with bradykinesia and impatience associated with akathisia. Since then, it has been customary to classify broadly the neuroleptic-induced extrapyramidal symptoms as either purely motor disturbances (e.g., dystonia, tremor) or mixed motor

and mental disturbances (e.g., akathisia, bradykinesia). Some clinicians have emphasized the existence of dysphoric states induced by neuroleptics, that is, generalized feelings of unwellness, which cannot be fully explained by the severity of motor disorders or are not associated with motor manifestations (19-21). A main characteristic of this dysphoric response to the medication is a distinctly unpleasant, affective quality of mentation associated with somatic complaints that often are vaguely expressed as "just not feeling right." Occasionally this response is described vividly as peculiar sensations, like the patient described by Van Putten and May (20) who complained that neuroleptic treatment had induced a "hangover without headache." We hypothesize that at least some of these dysphoric states may be sustained by unpleasant sensory phenomena.

The pathogenesis of primary sensory symptoms in parkinsonism is poorly understood. Given the general absence of gross lesions in the peripheral nervous system and central sensory pathways, several authors have suggested that these symptoms may be another manifestation of central dopaminergic deficiency relating to dysfunction of basal ganglia (2, 4, 22). There is some evidence that the basal ganglia somehow modify sensory perception, and electrophysiological studies indicate that striatal influences on sensory activity are mainly inhibitory (23). Snider et al. (4) speculated that spontaneous sensory symptoms could be related to release of sensory centers from extrapyramidal influence. Alternatively, Nutt and Carter (6) pointed out how the descending dopaminergic tracts projecting to both dorsal horn and midline thalamic nuclei (24, 25) provide an anatomical substrate for dopaminergic influence on sensory input and perception. Although the findings of our study do not substantially contribute to elucidating the pathogenesis of sensory symptoms, they are consistent with the view that reduced dopaminergic transmission by itself, in the absence of neuropathological lesions, may be a sufficient factor in the genesis of such symptoms.

In conclusion, it must be reiterated that although the results of this study are consonant with the hypothesis that neuroleptic treatment is associated with pain, their validity may be questionable. Until these findings are replicated in subsequent studies using psychometrically standard methods, no definitive conclusions can be reached.

Prevalence of Tardive Dyskinesia, Tardive Dystonia, and Respiratory Dyskinesia Among Chinese Psychiatric Patients in Hong Kong

Helen Chiu, M.R.C.Psych., Patrick Shum, M.R.C.Psych., F.R.A.N.Z.C.P.,
Joseph Lau, Ph.D., Linda Lam, M.R.C.Psych., and Sing Lee, M.R.C.Psych.

Objective: Only scanty information on the prevalence of tardive dyskinesia in Chinese patients has been available. This study was undertaken to examine the prevalence of tardive dyskinesia, tardive dystonia, and respiratory dyskinesia in Chinese psychiatric patients in Hong Kong. **Method:** All inpatients of a mental hospital in Hong Kong, except those in the admission and children's wards, were surveyed with the Abnormal Involuntary Movement Scale, and standard research criteria were used to establish the diagnosis of tardive dyskinesia. In addition, patients were screened for tardive dystonia, according to published criteria, and for respiratory dyskinesia by physical examination and laboratory tests. **Results:** Among the 917 patients surveyed, the prevalence rates were 9.3% for tardive dyskinesia, 0.4% for tardive dystonia, and 1.2% for respiratory dyskinesia. With multivariate analysis, greater age and a lower current dose of antipsychotic, but not the presence of mood disorder, were factors found to be significantly associated with tardive dyskinesia. **Conclusions:** The prevalence rates were much lower than those found in Western studies. This may indicate that there is an ethnic difference in the prevalence of these conditions. Prospective cross-cultural studies are necessary to explore this possibility.

(Am J Psychiatry 1992; 149:1081-1085)

Tardive dyskinesia is an involuntary movement disorder associated with prolonged use of neuroleptics. Kane and Smith (1) reviewed 56 studies involving 34,555 patients and found an average prevalence of 20%. In the same article, these investigators reviewed 19 studies on spontaneous dyskinesia and identified a prevalence of 5%. These were mostly American and European studies; information on Chinese patients is scanty.

Eleven Asian studies on the prevalence of tardive dyskinesia, involving 8,647 patients, have so far been published (2-12). The average prevalence is 11.6%, but the range is wide (2.5%-27.6%). This variability is multifactorial and may be due to differences in the methods of assessing dyskinesia, to sociodemographic and clinical characteristics, and/or to the fluctuating nature of tardive dyskinesia. In fact, earlier studies were fraught with methodological problems, such as use of variable

diagnostic criteria, methods of case finding, and examination techniques. In the three studies that examined a homogeneous population of Chinese patients, the Taipei study (3) did not provide details on diagnosis and methodology, the Hong Kong study (6) did not use a standardized instrument to assess dyskinesia, and the Shanghai study (10) involved only chronic schizophrenic patients.

Our first aim, therefore, was to examine the prevalence of tardive dyskinesia in various groups of Chinese psychiatric patients by using an improved method. In addition, we wished to examine the prevalence of tardive dystonia and respiratory dyskinesia. Tardive dystonia (13) is an underrecognized condition that is frequently more disabling than classical tardive dyskinesia. Although it may be a variant or subsyndrome of tardive dyskinesia, it is potentially useful to isolate it in epidemiological and treatment studies, since there is preliminary evidence that it differs from classical tardive dyskinesia in some significant ways (14). In this article, the term "tardive dyskinesia" is therefore confined to the bucco-linguo-masticatory syndrome and choreoathetoid movements of the limbs and trunk. Respiratory dyskinesia is characterized by irregularity in the rate, rhythm, and depth of breathing and usually occurs in patients with tardive dyskinesia (15).

^aRefers to patients currently taking antipsychotic drugs.

METHOD

Our survey was conducted from October to November 1989 in one of the three mental hospitals in Hong Kong. At the outset of the study, 30 randomly chosen patients were examined independently by two of the investigators (H.C. and L.L.), both psychiatrists, with the Abnormal Involuntary Movement Scale (AIMS) (16) to test interrater reliability. Kappas for the seven items of the AIMS ranged from 0.8 to 1.0.

All inpatients except those in the admission and children's wards were examined by one or the other of the two investigators (H.C. and L.L.) with the AIMS after informed consent had been given. Patients in the admission wards were excluded because they were mentally unstable and their clinical diagnoses were frequently uncertain. Clinical diagnoses had been made previously according to ICD-9 by the psychiatrists in charge of the patients. The investigators were blind to these diagnoses.

Schooler and Kane's research diagnostic criteria (17) were used to establish the diagnosis of tardive dyskinesia. Prerequisites include 1) exposure to antipsychotics for at least 3 months, 2) at least "mild" involuntary movements in two or more body areas or at least "moderate" involuntary movements in one or more body areas, and 3) absence of other conditions causing involuntary movement.

All patients were also examined for the presence of tardive dystonia according to the criteria of Burke et al. (13): 1) the presence of chronic dystonia, 2) history of antipsychotic drug treatment preceding or concurrent with the onset of dystonia, 3) exclusion of known causes of secondary dystonia by appropriate clinical and laboratory evaluation, and 4) no family history of dystonia. To exclude secondary causes of dystonia, affected subjects underwent further examination, including CBC, tests of liver, renal, and thyroid function, determination of ceruloplasmin and copper levels, and slitlamp examination.

In the examination for respiratory dyskinesia, patients were bared to the waist and respiration was observed for 3 minutes in both sitting and lying positions. Irregularity of breathing rate, rhythm, and depth was necessary for the diagnosis. Using such criteria, we

found that the presence or absence of respiratory dyskinesia was determined without difficulty. Affected patients were also examined for cardiac or lung disease and underwent a battery of tests, including ECG, chest X-ray, determination of serum electrolyte levels, liver function, and blood gases, and CBC. Polygraphic recordings of thoracic and abdominal respiratory efforts were performed to confirm the dyskinesia objectively.

All patients were subsequently interviewed. In addition, case notes and drug charts were reviewed for demographic data and family, psychiatric, and treatment histories.

Patients with tardive dyskinesia were reexamined with the AIMS 3 months after their initial interviews. Those who continued to meet the criteria for tardive dyskinesia were diagnosed as having persistent tardive dyskinesia (17).

The 95% confidence intervals of prevalence were calculated for the different diagnostic subgroups. Both univariate (Mann-Whitney test and chi-square test) and multivariate (logistic regression) analyses were used to identify the factors associated with tardive dyskinesia.

RESULTS

Nine hundred seventeen patients (503 male and 414 female) were surveyed, among whom 863 (94.1%) had histories of exposure to antipsychotic medication. Their mean age was 46.5 years (SD=18.0, range=16-103), and the mean duration of hospitalization was 3.1 years (SD=2.4). Seven hundred ninety-two (86.4%) of the patients were currently taking antipsychotic drugs (table 1). Their mean current dose of antipsychotic in chlorpromazine equivalents (18) was 876.3 mg/day (SD=853.1, median=600, range=10-4725). Patients were commonly prescribed one to three types of antipsychotic drugs; chlorpromazine was the most widely used, followed by trifluoperazine, haloperidol, and thioridazine (table 2). Of the 792 patients currently taking antipsychotics, 71.1% were given an anticholinergic drug (table 1). Trihexyphenidyl was the only anticholinergic drug used, and the mean daily dose was 6.29 mg (SD=3.02).

TABLE 2. Patients Currently Taking the Four Most Commonly Prescribed Antipsychotic Drugs in a Survey of 917 Chinese Psychiatric Patients in Hong Kong

Diagnosis	Patients Taking Chlorpromazine (N=336)		Patients Taking Trifluoperazine (N=221)		Patients Taking Haloperidol (N=195)		Patients Taking Thioridazine (N=145)	
	N	%	N	%	N	%	N	%
Schizophrenia	267	79.5	197	89.1	136	69.7	94	64.8
Manic-depressive psychosis, circular type	4	1.2	1	0.5	10	5.1	3	2.1
Manic-depressive psychosis, depressed type	3	0.9	2	0.9	0	0.0	2	1.4
Dementia	13	3.9	3	1.4	11	5.6	28	19.3

Other	14	4.2	9	4.1	15	7.7	13	9.0

Eighty-five patients had tardive dyskinesia (table 1), a prevalence of 9.3% (95% confidence interval=7.4%–11.2%). The mean age of these patients was 61.7 years (SD=15.9, range=24–94). Seventy-two (84.7%) of these patients had persistent tardive dyskinesia. No patients without a history of exposure to antipsychotics had dyskinesia.

The majority of the patients (N=602) were schizophrenic (table 1), among whom the prevalence of tardive dyskinesia was 8.5% (9.5% confidence interval=6.3%–10.7%).

Four patients (two of each sex) had tardive dystonia, a prevalence of 0.4% (95% confidence interval=0.1%–1.1%). Their mean age was 39.3 years (SD=1.1, range=38–41). The duration of dystonia ranged from 2 to 5 years. Two of these patients had coexistent tardive dyskinesia.

Eleven patients (three male and eight female) had respiratory dyskinesia, an overall prevalence of 1.2% (95% confidence interval=0.6%–2.2%) and a prevalence of 12.9% among those with tardive dyskinesia. Their mean age was 65.5 years (SD=16.0, range=38–89). Clinical and polygraphic characteristics of these patients will be presented in a separate paper.

Older age (Mann-Whitney test, $z=-7.9$, $p<0.0001$), female sex ($\chi^2=8.34$, $df=1$, $p=0.004$), lower current dose of antipsychotic (Mann-Whitney test, $z=-6.7$, $p<0.0001$), and a diagnosis of manic-depressive psychosis ($\chi^2=14.86$, $df=1$, $p=0.01$) were individually associated with a higher risk of tardive dyskinesia. Among schizophrenic patients, duration of mental illness was not significant.

Table 3 shows the logistic regression analysis of the significant variables. Schizophrenia was used as the reference for the category of diagnosis. Older age and a lower current dose of antipsychotic were still significantly associated with a higher risk of tardive dyskinesia, but sex lost its significance. Dementia and "other" diagnoses were associated with a lower risk of tardive dyskinesia.

DISCUSSION

We found a relatively low prevalence of tardive dyskinesia (9.3%) among Chinese psychiatric patients in Hong Kong. The prevalence of 8.5% among the schizo-

phrenic patients is remarkably similar to the 8.4% among chronic schizophrenic patients in Shanghai (10). This low prevalence is also similar to the average prevalence of 11.6% in other Asian studies (2–12). The Shanghai (10) and Indian (5) investigators attributed the low prevalence of tardive dyskinesia to the low dosage of antipsychotic used. In our study, the mean current dose of antipsychotic was 876.3 mg/day (SD=853.1) of chlorpromazine equivalents. This is at least comparable to the dosage commonly used in Western countries, even without adjusting for the generally lower body weight of the Chinese.

The reasons for our finding of a lower prevalence of tardive dyskinesia than that in Western studies are at present unclear. Recently, Tan and Tay (12) found in Singapore that the prevalence of tardive dyskinesia in Eurasians was higher than in Asians; they speculated that genetic differences in sensitivity to antipsychotics might be responsible. This possibility needs to be explored further in prospective cross-cultural studies.

An unexplored area in our survey is the effect of drug-induced parkinsonism on tardive dyskinesia. Although not unanimously confirmed, an inverse relation be-

tween tardive dyskinesia and drug-induced parkinsonism was previously reported and was attributed to a masking bradykinetic effect of parkinsonism on tardive dyskinesia (19, 20). The high frequency of use of anticholinergic drugs (71.1%) and the high mean current dose of antipsychotic in our survey indicate that drug-induced parkinsonism was common among our subjects and therefore makes this possible interaction particularly relevant to our study. Unfortunately, we did not assess drug-induced parkinsonism, and the possibility that suppression of tardive dyskinesia by drug-induced parkinsonism may have been responsible for the low prevalence of tardive dyskinesia needs to be explored in future studies.

The association of old age with a higher risk of tardive dyskinesia is expected (21). The association of a lower current dose of antipsychotic with a higher risk of tardive dyskinesia has also been reported (11). This may be due to the suppressing effect of a higher dose of antipsychotic on tardive dyskinesia and/or doctors' attempts to reduce antipsychotic dosage after tardive dyskinesia was detected.

Mood disorder was found to be associated with a higher risk of tardive dyskinesia in some studies that did not use multivariate analysis (22, 23). We failed to confirm this. Similarly, although organic brain damage has been reported to be a risk factor for tardive dyskinesia (24), in our study dementia was associated with a lower risk of tardive dyskinesia after we adjusted for age and current dose of antipsychotic.

So far, two small studies on tardive dystonia (25, 26) have found a prevalence of 1.5%–2%. If tardive dystonia is a subsyndrome of tardive dyskinesia (14), our finding of 0.4% is consistent with the lower prevalence of tardive dyskinesia in our patients. The mean age at onset of tardive dystonia in our group was 36.4 years, but the small number of patients precludes any firm conclusion about a younger age at onset of tardive dystonia (13, 25) than at onset of tardive dyskinesia. Of the four patients affected, "bizarre posture" and "histrionic look" were the only comments recorded in the case notes of three of them. This lends support to the idea that this still controversial condition is underrecognized (13).

There have been two previous studies on the prevalence of respiratory irregularity in chronic mental patients (27, 28). Yassa and Lal (27) found a prevalence of 2.3% in 351 chronic inpatients and a prevalence of 7.4% among those with tardive dyskinesia (ages unknown). In contrast, Youssef and Waddington (28) reported the high prevalence of 45% among 76 patients who suffered from schizophrenia, bipolar disorder, and mental handicap in addition to tardive dyskinesia. Since respiratory dyskinesia is probably more common in the elderly, the relatively old age (mean=63.6 years) of their sample might have inflated the prevalence rate. Our finding of 1.2% is a low figure.

One obvious limitation of our study is its cross-sectional design, which precludes accurate judgment about risk factors and causal relationships. Prospective cross-

cultural studies, albeit difficult and costly, are needed in the future. The second limitation is the lack of information on the cumulative antipsychotic dose, which is virtually impossible to obtain in our local setting. Instead, the current daily dose of antipsychotic was used, and this has a rather different implication. Third, the clinical diagnoses were made by the psychiatrists in charge of the patients according to ICD-9, which did not provide standard diagnostic criteria. It therefore remains possible that there were misdiagnoses, especially confusion between schizophrenia and manic-depressive psychosis (29), for some of the survey patients. While this may have led to an inaccurate representation of patients in the various diagnostic categories, it should not have affected the overall prevalence of tardive dyskinesia found in our study.

CSF β -Endorphin and Dynorphin in Bulimia Nervosa

Timothy D. Brewerton, M.D., R. Bruce Lydiard, Ph.D., M.D.,
Michele T. Laraia, R.N., M.S.N., Jennifer E. Shook, Ph.D.,
and James C. Ballenger, M.D.

Objective: Preclinical and clinical evidence suggests that central opioid dysfunction may play a role in the pathophysiology of the eating disorders. In particular, endogenous opioids are known to regulate feeding behavior, mood, perception, and neuroendocrine function, all of which are disturbed in patients with eating disorders. Although low concentrations of CSF β -endorphin have been reported in low-weight patients with anorexia nervosa, central opioid activity in normal-weight patients with bulimia nervosa has not been reported. The authors therefore measured CSF concentrations of β -endorphin and dynorphin in drug-free female patients with DSM-III-R-defined bulimia nervosa and normal comparison subjects. **Method:** After 4 days of a low monoamine diet and overnight bed rest, CSF was obtained (12–26 cc) from 11 women with bulimia and 17 normal comparison subjects (eight women and nine men). **Results:** The women with bulimia had significantly lower CSF concentrations of β -endorphin than did the female comparison subjects. However, CSF concentrations of dynorphin were not significantly different in patients and female or male comparison subjects. β -Endorphin concentrations were inversely correlated with Beck Depression Inventory scores and the depression subscale of the Eating Disorders Inventory. **Conclusions:** These data support a role for central opiates in the mediation of the pathophysiology of the signs and symptoms of bulimia nervosa, although it is impossible to rule out the effects of depression on the results. (Am J Psychiatry 1992; 149:1086–1090)

Preclinical and clinical evidence suggests that alterations in endogenous opioid function are associated with alterations in feeding (1–8), mood (8, 9), perception (8, 10), and neuroendocrine function (11), all of which are characteristic of patients with eating disorders. In animals, opioid agonists increase and opioid antagonists decrease food intake. These effects appear to be mediated by several receptor types, including κ , μ , δ , and σ receptors (12, 13). A disturbance of opioid function could also contribute to the hypercortisolism observed in anorexia nervosa (14, 15). Kaye and associates found that underweight patients with anorexia nervosa had significantly lower CSF β -endorphin concentrations than healthy volunteers (16). These low CSF β -endorphin concentrations normalized after weight restoration. Lower concentrations of plasma β -endorphin have been reported in normal-weight pa-

tients with bulimia nervosa (17, 18). However, it is highly questionable whether plasma β -endorphin reflects central β -endorphin function. CSF levels of β -endorphin, as well as of dynorphin, have not been reported in normal-weight patients with bulimia nervosa. We therefore studied CSF levels of β -endorphin and dynorphin in a group of normal-weight patients with bulimia nervosa and healthy comparison subjects.

METHOD

Patients and comparison subjects were recruited through local newspaper advertisements and then interviewed with the Structured Clinical Interview for DSM-III (19), which was modified for DSM-III-R diagnosis. Patients with bulimia nervosa were included if they had experienced binge eating and purging at least three or more times per week for at least 6 months before the study. The mean weekly binge frequency was 8.2 times (SD=5.2) (range=3–19), and the mean weekly vomiting frequency was 4.7 times (SD=6.4) (range=0–19). Five patients had concurrent DSM-III-R-defined major depression, and six did not. Comparison subjects were ex-

Received Jan. 30, 1991; revisions received Oct. 8 and Dec. 18, 1991; accepted Jan. 10, 1992. From the Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina. cluded if they had a lifetime or family history (first-degree relatives) of any major psychiatric illness. In addition, all comparison subjects were free of significant medical illnesses on the basis of a physical examination and routine laboratory tests. The study subjects consisted of 11 bulimic women and 17 normal comparison subjects (eight women and nine men). The mean age was 30.2 years (SD=6.4) for the women with bulimia, 35.5 years (SD=7.6) for the female comparison subjects (n.s.), and 26.7 years (SD=3.9) for the male comparison subjects (n.s.). Mean percent of average body weight was 102.6% (SD=13.1%) for the women with bulimia, 111.8% (SD=22.4%) for the female comparison subjects (n.s.), and 113.0% (SD=16.0%) for the male comparison subjects (n.s.); standardized weight tables were used (20).

All subjects were medication free for at least 4 weeks before the study. In addition, all subjects had a low monoamine diet for 4 days before CSF samples were obtained. Outpatient subjects were admitted to a clinical research unit on the night before the study. All subjects fasted after midnight, were kept at bed rest for 9 hours, and were allowed up only to go to the bathroom. Lumbar punctures were performed between 8:00 a.m. and 9:00 a.m., with subjects in the lateral decubitus position. CSF samples were immediately placed on wet ice, aliquoted, and frozen at -70°C . Samples were assayed in duplicate for β -endorphin₁₋₃₁ and dynorphin A₁₋₈ by radioimmunoassay (21, 22). Samples were diluted with radioimmunoassay buffer (pH=7.4, 0.02 M phosphate buffer containing 0.15 N NaCl, 0.1% bovine serum albumin, 0.01% thimerosal, and 0.1% triton-X-100) and were incubated overnight (18–24 hours) at 4°C with antiserum and ^{125}I -labeled tracers specific for dynorphin A₁₋₈ or β -endorphin₁₋₃₁. Free and bound tracers were separated by the addition of a 3% charcoal slurry and subsequent centrifugation ($2,500 \times g$ for 10 minutes at 4°C). The antiserum for dynorphin A₁₋₈ has 0.02% and 0.01% cross-reactivities for dynorphin A₁₋₁₃ and dynorphin A₁₋₁₇ and does not cross-react with met-enkephalin or leu-enkephalin. The sensitivity of this assay was 5 fmol/ml. The antiserum for β -endorphin₁₋₃₁ has 50% cross-reactivity with β -lipotropin and no cross-reactivity with met-enkephalin or α - or γ -endorphin. The sensitivity of this assay was 50 pg/ml.

Before the procedure, one of the investigators administered the Hamilton Rating Scale for Depression (23) and the Hamilton Rating Scale for Anxiety (24). In addition, subjects completed a series of psychological rating scales, including the Eating Disorders Inventory (25), the Eating Attitudes Test (26), the Beck Depression Inventory (27), and the Symptom Distress Checklist (SCL-90-R) (28) before lumbar puncture.

Statistical analysis was carried out by using the Statistical Analysis System (29). Between-group comparisons were performed with analysis of variance (ANOVA) and Student's *t* test. Correlations were determined with Spearman's rank order correlation (r_s) and were then corrected for number of comparisons.

FIGURE 1. CSF Levels of β -Endorphin in 10 Bulimic Women and Eight Female and Eight Male Comparison Subjects^a

^aLevels of one bulimic woman and one male comparison subject were below the detectable limits of the assay (5 pg/ml) and were not included in the analysis. Horizontal lines represent means. Significant differences in CSF levels of β -endorphin were found among the three groups ($F=4.39$, $df=2, 24$, $p \leq 0.03$, ANOVA).

^bPost hoc differences persisted between bulimic women and female comparison subjects ($p \leq 0.05$, Bonferroni *t* test).

RESULTS

There was a significant difference in the CSF levels of β -endorphin between female patients with bulimia nervosa (mean=71.9 pg/ml, SD=23.0), female comparison subjects (mean=98.0 pg/ml, SD=17.7) ($p \leq 0.02$, unpaired *t* test), and male comparison subjects (mean=99.3 pg/ml, SD=19.3) ($p \leq 0.03$, ANOVA) (figure 1). (The β -endorphin levels of one bulimic patient and one male comparison subject were below the detectable limits of the assay [5 pg/ml] and were not included in this analysis.) After post hoc corrections, significant differences persisted between women with bulimia and female comparison subjects ($p \leq 0.05$, Bonferroni *t* test). There was a trend for differences in the CSF levels of dynorphin among women with bulimia (mean=21.3 pg/ml, SD=7.8), female comparison subjects (mean=22.7 pg/ml, SD=8.3), and male comparison subjects (mean=28.8 pg/ml, SD=6.0) ($p \leq 0.09$, ANOVA) (figure 2). However, there were no significant post hoc differences. CSF levels of β -endorphin and dynorphin were not significantly correlated to age or percent of average body weight in any of the groups or in the total cohort.

CSF levels of β -endorphin and dynorphin were correlated with several behavioral rating scales. CSF β -endorphin levels were significantly correlated with the Beck Depression Inventory ($p=0.0009$) (figure 3), the depression subscale score of the Eating Disorders Inventory ($p=0.001$) (figure 3), and the anger/hostility subscale of the SCL-90-R ($N=10$, $r_s=0.65$, $p=0.04$). There was a trend for CSF β -endorphin to be correlated

FIGURE 2. CSF Levels of Dynorphin in 11 Bulimic Women and Eight Female and Nine Male Comparison Subjects^a

^aHorizontal lines represent means. There was a trend for differences in CSF levels of dynorphin among bulimic women and female and male comparison subjects ($F=2.74$, $df=2, 25$, $p<0.09$, ANOVA).

with the Hamilton anxiety scale ($N=10$, $r_s=-0.62$, $p=0.06$). After Bonferroni corrections for the number of comparisons made, only the correlations between CSF β -endorphin levels and the two ratings of depression (Beck Depression Inventory and subscale score of the Eating Disorders Inventory) remained significant ($p\leq 0.02$). It should be noted that figure 3 includes an open circle that represents one bulimic subject whose β -endorphin levels were below the detectable limit of the assay (5 pg/ml), and although data on this patient were *not* included in the statistical analysis, they do support the relationship between low β -endorphin levels and high levels of depression.

CSF dynorphin concentrations were inversely correlated with weekly binge frequency ($N=11$, $r_s=-0.64$, $p=0.03$), Eating Attitudes Test scores ($N=11$, $r_s=-0.61$, $p=0.006$), and the thin subscale scores of the Eating Disorders Inventory ($N=11$, $r_s=-0.65$, $p=0.03$). There were trends for CSF dynorphin levels to be correlated with the interpersonal distrust subscale scores of the Eating Disorders Inventory ($N=11$, $r_s=0.55$, $p<0.1$) and the maturity fear subscale scores of the Eating Disorders Inventory ($N=11$, $r_s=-0.60$, $p=0.07$). However, none of these correlations involving CSF dynorphin levels remained significant after Bonferroni corrections.

Given the relationship with depression noted earlier, we compared CSF opiate levels in bulimic patients with and without concurrent major depression. There was a trend for depressed patients to have lower CSF β -endorphin concentrations ($N=4$, mean=55.6 pg/ml, $SD=16.5$) than nondepressed patients ($N=6$, mean=82.7 pg/ml, $SD=20.8$) ($t=2.18$, $df=8$, $p<0.07$). There was not a significant difference in CSF dynorphin concentrations between depressed ($N=5$, mean=17.2 pg/ml, $SD=6.5$) and nondepressed ($N=6$, mean=24.7 pg/ml, $SD=7.6$) women with bulimia nervosa ($t=1.76$, $df=9$, $p=0.11$).

FIGURE 3. Correlation Between CSF β -Endorphin Levels and Depression Scores in 10 Bulimic Women^a

^aCSF β -endorphin levels were significantly correlated with Beck Depression Inventory scores ($r_s=-0.87$, $p=0.0009$) and the depression subscale score of the Eating Disorders Inventory ($r_s=-0.87$, $p=0.001$). The open circle represents one subject whose β -endorphin levels were below the detectable limits of the assay (5 pg/ml) and is not included in this analysis.

DISCUSSION

This is the first report of lower CSF β -endorphin concentrations in normal-weight patients with bulimia nervosa than in female age-related comparison subjects. However, CSF dynorphin concentrations were not significantly different among groups. Our results are similar to the results reported by Kaye and colleagues, who found that CSF concentrations of β -endorphin and other peptides were low in patients with anorexia nervosa (16). However, the levels normalized after long-term stabilization of feeding and weight. The weights of our patients were not significantly different from those of their healthy comparison counterparts, and neither β -endorphin nor dynorphin concentrations in CSF were significantly correlated with percent of average body weight in any of the groups. Nevertheless, it is likely that our patient population, like that of others (30–32), had some degree of chronic semistarvation or malnutrition as a result of intermittent restriction of food intake. Although it was not statistically significant because of the large degree of variance, the fact that the weight of the bulimic patients was 9.2% of average body weight less than that of the comparison subjects may be clinically significant. Evidence suggests that patients with bulimia nervosa may have a higher set point for weight maintenance and could therefore be mildly underweight relative to their own “ideal” body weight (which is usually above the population weight) (33). This could conceivably result in low β -endorphin concentrations, possibly as a result of low levels of estrogen, which has been shown in animals to be necessary for the release of hypothalamic β -endorphin (34). In addition, acute food deprivation in rats results in elevations of pituitary β -endorphin immunoreactivity but not dynorphin content (35). Furthermore, binge eating and vomiting are likely to

result in secretion of corticotropin-releasing hormone (CRH), since plasma cortisol has been reported to increase after these behaviors (36) and to remain elevated (37). Unfortunately, plasma cortisol levels are not available from our group for comparison. One possible interpretation of these data may be that the stress of binge eating and purging leads to the release of CRH and the stimulation of the hypothalamic-pituitary-adrenal axis, including the pro-opiomelanocortin molecule from which β -endorphin is cleaved. Subsequent peptide depletion and/or opiate receptor down-regulation because of chronic binge eating, purging, and/or semistarvation may result in decreased CSF β -endorphin over time. This hypothesis is compatible with recent findings of reduced pain sensitivity in patients with eating disorders (38).

CSF levels of β -endorphin were highly correlated with two depression scales, and there was a trend for depressed women with bulimia to have lower levels than non-depressed patients. The reason for the lack of correlation with the Hamilton depression scale is unclear, but it may relate to less patient self-disclosure in an interview situation. It is impossible to say definitely whether the lower CSF concentrations of β -endorphin are due to depression or bulimia or an interaction between the two. A group of depressed nonbulimic patients was not available for comparison. However, other investigators have found no differences in β -endorphin or β -endorphin immunoreactivity between depressed patients and normal (39–41) or neurological (42) comparison subjects. In addition, no relationship between major depression and CSF β -endorphin levels was found in a group of patients with low back pain (43). Lower CSF β -endorphin levels have been reported in patients with alcohol dependence (44) and severe migraine (45), both of which may be related to bulimia (46, 47). Further studies of the relationship between CSF β -endorphin concentrations and depression are warranted.

Our findings also suggest that alterations of central opioid function may contribute to alterations in perception and behavior in patients with bulimia nervosa. Although levels of dynorphin were initially inversely correlated with weekly binge frequency, Eating Attitudes Test scores, and several subscale scores of the Eating Disorders Inventory, these correlations disappeared after correction for the large number of correlations performed. Nevertheless, this leaves open the possibility that dynorphin may be involved in an array of disturbances related to eating disorder pathology including binge eating, compulsivity, and body image distortion (10, 48, 49). Dynorphin is reported to play a major role in the modulation of the effects of other opiates and can have opposite effects on analgesia and temperature, as well as motor, cardiovascular, and respiratory effects, depending on the baseline state of the organism (48).

Research conducted in the field during the past two decades has clearly demonstrated that food intake is controlled by multiple neurotransmitters in the brain that are responsive to a complex array of metabolic, hormonal, and neural signals. Peptides have an important function in feeding, in part through their interac-

tion with monoamines (5, 50–52). It is also clear from studies of patients with eating disorders that several neuroregulatory systems are disturbed (53–55). It is therefore imperative that the available data be integrated into a comprehensive theory encompassing all involved systems, including the opiate system, if these findings are confirmed.

A Monozygotic Mirror-Image Twin Pair With Discordant Psychiatric Illnesses: A Neuropsychiatric and Neurodevelopmental Evaluation

James B. Lohr, M.D., and H. Stefan Bracha, M.D.

One piece of genetic evidence for the biological distinctness of schizophrenia and bipolar illness is the rarity of monozygotic twin pairs in which one twin suffers from schizophrenia and the other from bipolar disorder. The authors describe a pair of monozygotic mirror-image twins with discordant diagnoses, schizophrenia in one twin and bipolar or schizoaffective disorder in the other.

(Am J Psychiatry 1992; 149:1091-1095)

Since Kraepelin first clearly divided the major mental illnesses into the broad categories of "dementia praecox" and "manic-depressive illness," researchers have puzzled over the relationship of these two conditions. Until 1982 there were no reports of twin pairs in which one twin suffered from schizophrenia and the other from bipolar disorder (1). In 1982 McGuffin et al. (2) reported identical male triplets, two of whom were diagnosed as having schizophrenia and the third of whom had bipolar illness. More recently, Dalby et al. (3) reported identical male twins, one of whom was reliably diagnosed as having schizophrenia and the other of whom had a diagnosis of mania. Studies of monozygotic twins have revealed very few pairs discor-

dant for schizophrenia and bipolar disorder, which supports the biological distinctness of schizophrenia and bipolar illness. Most of the other available genetic evidence also supports the distinctness of the two conditions (1, 4, 5), although there is some disagreement (6, 7).

The present paper is a neuropsychiatric study of one pair of monozygotic twins who appear to be discordant for schizophrenia and either bipolar illness or schizoaffective disorder. An interesting and unusual feature of these twins is that they are mirror images of one another.

CASE REPORTS

Both twins received physical examinations, CT scans, EEGs, and medical workups including thyroid function tests, CBC, electrolyte measurements, and urinalysis. All the results were within normal limits. Apart from a brief history of mild cannabis abuse, there was no history of substance abuse in either twin and no other evidence that the mental disorder was secondary to organic factors. Their prenatal and birth histories were unremarkable. There was no known family history of major mental illness.

Twin 1. This twin was first hospitalized at the age of 22 after several months of severe auditory and visual hallucinations and delusions. She was withdrawn, would make bizarre

comments such as "I'm an airplane," and would talk to people who were not present. While in church she would suddenly start laughing, stating that people were telling her jokes. She would often stare into space while mumbling to herself, and her thoughts were fragmented or loosely associated.

Over the next 3 years she was hospitalized several times and treated with high-potency neuroleptics with minimal or no effect. After nearly 4 years of severe psychosis, haloperidol treatment eventually resulted in improvement. She first came under our care when she was 27 years old, and the haloperidol treatment was discontinued during the course of a research study. She became very psychotic and experienced auditory and visual hallucinations, talking to herself and claiming to be in heaven with angels surrounding her and talking to her. When she was again treated with haloperidol, 20 mg/day, her symptoms almost completely resolved and she was able to work as a secretary for several years. The haloperidol dose was gradually reduced, but at 5 mg/day she suffered a severe psychotic decompensation and was rehospitalized. She was restabilized with haloperidol decanoate injections, 100 mg every 2 weeks. Although not yet able to return to work, she is able to function independently at this time. This patient has been given diagnoses only of chronic paranoid or chronic undifferentiated schizophrenia on the basis of both the Schedule for Affective Disorders and Schizophrenia (SADS) and DSM-III.

Twin 2. This twin was prone to rapid mood swings and angry outbursts since childhood, and at age 19 she developed severe depression and anxiety. She also described a vague sensation that people were staring at her and manipulating her and stated that her vision would become very acute and vivid, although for only very short periods. She once said she felt as though "a force like a boyfriend of mine grabbed me and took me into the bedroom, although no one else was around." She also felt at one point as though her father's emotions would "come through" her but was vague about exactly what this meant. She consistently denied hallucinations, and there was no loosening of associations.

Later in the course of her illness, she described episodes in which she had to go "faster and faster." At one point she wished to give up everything and become an artist, stating that she could be "the greatest artist in the world." She was grandiose, irritable, very talkative, and easily distracted, and she slept poorly. During the course of her illness she was treated with lithium, perphenazine-amitriptyline, haloperidol, thioridazine, desipramine, amitriptyline, fluphenazine, and carbamazepine. None of these medications was clearly effective.

At age 27 she was admitted to a private hospital because she was having severe mood changes, including depression and anger, and suicidal thoughts. Her self-esteem was poor and she felt inferior to others. Her speech was pressured and she fidgeted continually. She was treated with trifluoperazine, although there was no evidence of psychosis. Her mood partially stabilized, and she was discharged on a regimen of trifluoperazine with the diagnosis of schizoaffective disorder.

Later that year she began feeling very depressed and stayed in bed for 4 months. She slept 14 to 18 hours a night, gained 13 lb, and experienced fatigue and loss of energy. She lost interest in many of her hobbies, withdrew socially, and developed feelings of worthlessness and occasional thoughts of suicide. She was noted to spend a lot of time in front of the mirror, and she commented negatively on her appearance, stating she had developed a "cow neck" and severe acne—neither of which was true. Her memory and concentration were poor. She claimed her family was unfair to her, but she could give

no specific examples. She denied having hallucinations or delusions. A SADS interview provided a diagnosis of manic-depressive illness.

Over the following year she had numerous irritable outbursts, depressive episodes, and suicidal thoughts. She never had frank delusions or hallucinations and never manifested the bizarre behavior or fragmentation of thought seen in her twin sister. Occasionally she would have racing thoughts and would strike people without provocation. She was treated with lithium for several months without effect. Over the past several years her mood has stabilized and she has been functioning productively in a secretarial position. Her only medications have been small doses of haloperidol (usually 1 mg/day) for agitation or fluoxetine for depression.

LABORATORY AND INVESTIGATIVE PROCEDURES

Zygoty was determined by blood group analysis at the Immunogenetics Laboratory of Johns Hopkins Hospital, by using the method of Wilson (8). Blood typing is the most reliable method for assigning zygoty to twins (9). The probability of monozygoty was determined to be 0.9999941 (the probability of dizygoty was 0.0000591).

Handedness was determined by using the Edinburgh Inventory (10) and the Annett Handedness Preference Questionnaire (11). Additional tests were used to determine footedness and eyedness. Twin 1 was determined to be fully right-handed, right-footed, and right-eyed, and twin 2 was determined to be fully left-handed, left-footed, and left-eyed.

Both twins had 12 years of education. According to the Wechsler Adult Intelligence Scale, their full-scale IQs were 85 and 86, respectively. Twin 1 had a verbal IQ of 89 and a performance IQ of 84, and twin 2 had a verbal IQ of 86 and a performance IQ of 92.

Two slices from the CT scans of the twins, taken at similar levels, are presented in figure 1. The ventricle-brain ratios (VBRs) of twin 1 and twin 2 were 11.6 and 7.9 for the slices at level A and 11.0 and 10.9 for the slices at level B. The occipital regions of the twins appear to be mirror image; twin 1 demonstrates a wider right occipital lobe, and twin 2 has a wider left occipital lobe. When the method of Luchins et al. (12) was applied, the ratios of the left occipital width to the right occipital width for twin 1 were 1.05 (slice A) and 1.11 (slice B), whereas for twin 2 they were 0.94 (slice A) and 0.90 (slice B).

Photographs of the faces of the twins were made and measured according to the method of Sackeim et al. (13). Although several asymmetries were seen, the most interesting asymmetries occurred when the patients smiled. In the measurement of the lateral point of the nostril to the corner of the mouth, twin 1 showed a more pronounced and elevated smile on the right side, whereas twin 2 had a more pronounced smile on the left side.

We performed a standard ridge count and fingerprint pattern examination of the two twins (14). With standard ink techniques hand prints were obtained on both

FIGURE 1. CT Scans of Monozygotic Mirror-Image Twins With Discordant Psychiatric Disorders^a

^aTwin 1 (left) had schizophrenia, and twin 2 (right) received diagnoses of bipolar or schizoaffective disorder. The respective scans for the two twins were taken at approximately similar levels. Right and left orientation is the same for all slices, and the right hemisphere is on the reader's left.

hands for both twins. The quality of the fingerprints allowed pattern identification but only incomplete identification of ridge counts. The results available are presented in figure 2. Two facts are evident from examination of the twins' dermatoglyphics: 1) the similarity is greater in the mirror (heterolateral) comparison than in the standard (homolateral) comparison, and this similarity suggests again that these are mirror-image twins; 2) the degree of similarity is low, and the fingerprints do not appear "twin-like," especially in the standard comparison. These monozygotic twins likely would have been misclassified as fraternal in older studies, e.g., the study by Slater (15).

DISCUSSION

Over the 6 years that we have followed these twins, the diagnosis of twin 1 has never been in doubt. Twin 2

FIGURE 2. Dermatoglyphics of Monozygotic Mirror-Image Twins With Discordant Psychiatric Disorders^a

^aThe standard (homolateral) similarity score was 4, whereas the mirror (heterolateral) similarity score was 6 (i.e., higher). U=ulnar loop, W=whorl, R=radial loop.

has had a more confusing clinical picture, initially having symptoms suggestive of schizophrenia but later having symptoms of depression and mania and receiving diagnoses of bipolar or schizoaffective disorder. Although we are not yet prepared to give a definite diagnosis of bipolar illness to twin 2, it is clear that she has had much greater mood instability and much less psychosis than her sister.

Before we discuss the differences in clinical symptoms in these twins, the dermatoglyphic findings deserve comment. Dermatoglyphics have been used in twin studies to help determine zygosity (most such studies were before 1970). The assumption in many of these studies (15, 16) that dermatoglyphics are purely "genetic" markers has since proved to be false. Research since 1970 has shown that dermatoglyphics may be affected substantially by second-trimester prenatal insults, such as rubella, cytomegalovirus, and other viral infections (17). These considerations may have special relevance for monozygotic twin studies of schizophrenia (17, 18). The low dermatoglyphic similarity in this pair of monozygotic twins, whose zygosity was verified by human lymphocyte antigen testing, is consistent with a prenatal insult.

It is not clear why these monozygotic twins have such different presentations. Because twin 1 clearly has schizophrenia, we considered whether twin 2 has an atypical presentation of the same process—perhaps related to a milder prenatal insult, as just discussed. If this

is the case, then two of the possibilities that might account for the different symptoms are that 1) the twins have suffered the same disease process but with different degrees of severity, and 2) the mirroring is in some way related to the symptoms.

Differences in Severity

It is possible that twin 2 simply has a milder case of the same condition afflicting twin 1. This may be reflected in the ventricular size, because twin 1 has larger ventricles than twin 2, which is in keeping with reports of larger ventricles in the schizophrenic members of twin sets discordant for schizophrenia (19, 20) (although patients with mood disorders have also been reported to have large ventricles; see reference 21). Nevertheless, the notion that severity alone can account for the clinical differences strikes us as unlikely. We have observed both twins at different levels of severity throughout their respective illnesses, and they are consistently very different psychiatrically. Twin 1 manifests much more psychosis, and twin 2 demonstrates greater mood lability at all levels of severity.

Differences Related to Mirroring

It is tempting to speculate that the clinical differences may relate to the twins' being mirror images. Whether monozygotic twins become identical or mirror image is believed to be associated with the timing of the egg's splitting. If the egg splits earlier (the rule), both twins will be either right- or left-handed. If it splits later (which is uncommon), they will be opposite handed (22).

We have documented that these twins have opposite handedness, footedness, eyedness, facial asymmetry, fingerprint patterns, and emotional gesturing (asymmetric facial expression when smiling). The twins also have opposite occipital lobe asymmetry. The more commonly observed occipital asymmetry (in which the left occipital lobe is larger than the right) was reversed in the schizophrenic twin but was preserved in the affectively ill twin, a finding that supports previous reports in the literature (12, 23, 24).

If the differences in clinical presentation are in some way related to mirroring, what could be the nature of this relationship? It is possible that the same process affected both twins but the differences in brain organization, related to the mirroring process itself, contributed to the differences in clinical symptoms. For example, one of us (25) has proposed that the left hemisphere may be more susceptible to damage because it lags behind the right hemisphere during certain phases of prenatal development, thus placing it at greater risk for prenatal damage. It is possible that, because of mirroring, in twin 2 it was the right hemisphere that lagged behind and thus suffered more damage. Another possibility is that an asymmetrical insult affected the left hemispheres of both twins. In twin 1, who is right-handed, the damage occurred in a "typi-

cal" left hemisphere, but in twin 2, because of the mirroring, the left hemisphere might actually function more like a right hemisphere. Either of these two possibilities would imply that similar damage might cause either more psychosis or more mood disorder, depending on whether the left hemisphere or the right hemisphere is more affected.

Of course, these are only a few of many speculations that could be made regarding these cases. We believed the cases would be of interest to investigators and clinicians concerned with schizophrenia and mood disorders and to those interested in the importance of neurodevelopment and laterality of brain function.

Effective immediately, Letters to the Editor critical of an article published in the *Journal* must be received within 6 weeks of the article's publication; Letters from outside the United States must be received within 12 weeks. Letters received after the deadline will not be considered and will be returned unreviewed.

Interictal Psychiatric Morbidity and Focus of Epilepsy in Treatment-Refractory Patients Admitted to an Epilepsy Unit

Rahul Manchanda, M.B.B.S., M.D., M.R.C.Psych., F.R.C.P.(C), Betsy Schaefer, B.A., Richard S. McLachlan, M.D., F.R.C.P.(C), and Warren T. Blume, M.D., F.R.C.P.(C)

Of 71 consecutive patients admitted to an epilepsy unit of a general hospital, 32 (45%) were classified as having psychiatric disorders by using the General Health Questionnaire. No differences were evident to support a specific relationship between the type or focus of epilepsy and psychopathology.

(Am J Psychiatry 1992; 149:1096-1098)

Several studies attest to higher rates of psychiatric morbidity in epileptic patients (1-4). Furthermore, a particularly strong association between temporal lobe epilepsy and psychiatric disorders has been supported by some investigators (1-3, 5, 6) but not by others (7-10). A general practice survey (4) showed a difference in the frequency of psychiatric disturbance between focal and primary generalized epilepsy but not between temporal and focal nontemporal lobe epilepsy. Thus, the controversy regarding psychiatric illness in patients with temporal lobe epilepsy continues.

This study was carried out primarily to determine whether the prevalence and degree of psychopathology in patients with intractable epilepsy warranted routine psychiatric assessment as part of the investigation for epilepsy surgery. Another aim was to determine whether patients with a temporal lobe focus of seizures have a higher prevalence of psychopathology. Furthermore, the possibility of a relationship between laterality of seizure focus and psychiatric disturbance was investigated.

METHOD

The sample for this study consisted of all consecutive adult (age 16 and older) patients with epilepsy admitted to an epilepsy unit of a general hospital during a 20-month period. All patients were refractory to medical treatment and were admitted for assessment for neurosurgical intervention. Patients were considered treatment refractory if they continued to experience

seizures with an average frequency of at least once every month even with polytherapy using up to three different anticonvulsants for a period of at least 2 years. The seizure disorder was categorized according to the classification of the International League Against Epilepsy (11). All patients had standard EEG telemetry using scalp electrodes with continuous monitoring until sufficient seizures were recorded to delineate the focus. When scalp recordings failed to do this, telemetry was continued with implanted subdural electrodes.

In addition to this standard investigation, all patients were asked to fill in the self-administered 60-item General Health Questionnaire (12). A score of 12 or higher on this questionnaire identifies respondents with a non-psychotic psychiatric illness. The reliability and validity of the questionnaire has been extensively studied (12, 13), and the questionnaire is widely accepted as a screening instrument for defining psychiatric illness in medically ill populations.

RESULTS

Seventy-one patients admitted to the epilepsy unit were included in the sample. Thirty-six (51%) of the patients were men, and 35 (49%) were women. Their mean age was 29 years (SD=10.14). Forty-four (62%) were single, and 23 (32%) were married; four patients were separated or widowed. Their mean age at onset of epilepsy was 12.2 years (SD=9.4), the mean duration of their epilepsy was 16.8 years (SD=8.62), and their mean number of seizures per week was 9.6 (SD=17.8). Thirty-five (49%) of the patients had simple or complex partial seizures, 28 (39%) had simple or complex partial seizures with secondary generalization, and eight (11%) had primary generalized seizures. The primary seizure focus was categorized as temporal in 47 (66%)

Received July 9, 1991; revision received Dec. 10, 1991; accepted Jan. 10, 1992. From the Department of Psychiatry and the Department of Clinical Neurological Sciences, University Hospital. of the patients, nontemporal in 17 (24%), and indeterminate in seven (10%). Differences among these groups on demographic variables were examined by using a chi-square test for categorical variables; no significant differences were found. Of the 47 patients who had temporal lobe epilepsy, 19 (40%) had a left-sided focus, 20 (43%) had a right-sided focus, and eight (17%) were bitemporal.

According to their responses on the 60-item General Health Questionnaire, 32 (45%) of the 71 patients were categorized as having psychiatric disorders (their scores were 12 or higher). When having a General Health Questionnaire score of 12 or higher was compared with the seizure focus by using a chi-square test for comparison of means (table 1), no significant differences were observed ($\chi^2=0.75$, $df=2$, $p=0.69$). When General Health Questionnaire scores and laterality of seizure focus were compared, no significant differences were observed; 10 (48%) of the 21 patients with a temporal focus who were identified as having psychiatric disorders had a left temporal focus, and five (56%) of the nine patients with a nontemporal focus who were identified as having psychiatric disorders had a right nontemporal focus.

DISCUSSION

The highest frequency of psychiatric morbidity in epileptic patients is seen among institutionalized patients and those attending clinics specializing in the treatment of intractable seizure disorders (14). Using the General Health Questionnaire, we identified 32 (45%) of our 71 patients as having psychiatric disorders. These findings are consistent with those of Edeh and Toone (4), whose case material was unselected and community based. However, our results are probably an underestimate given that the sample consisted of a group of patients with more severe, treatment-refractory epilepsy. One or more of the following factors may account for this. Uncooperative, disturbed patients and those with serious psychiatric problems were less likely to be admitted to this inpatient epilepsy unit, where testing procedures require considerable cooperation and patience from the subjects. Furthermore, the General Health Questionnaire is a measure of nonpsychotic emotional illness and does not detect personality disorders.

Gibbs's findings that psychiatric disorders are three times more common among patients with temporal focal epilepsy than among patients with extratemporal focal epilepsy (5) remains controversial (4). This study also fails to support such a claim. In addition, we found no differences based on laterality of the seizure focus, which have been reported by some investigators (15, 16). However, studies supporting relationships between laterality of seizure focus and psychopathology looked at specific aspects of psychopathology that were not assessed in this study.

It may be argued that the General Health Questionnaire measured anxiety related to admission for possi-

^aData were missing for one patient with indeterminate focus.

ble neurosurgical treatment. The data do not support this. First, examination of the mean scores on subscales of the General Health Questionnaire shows that although the mean anxiety score was the highest in the total sample, the patients with a General Health Questionnaire score of 12 or higher scored highest on the somatic subscale. Second, our preliminary analysis of the General Health Questionnaire scores of a similar group of patients assessed during hospitalization and 1 year later as outpatients (these patients did not have neurosurgery) did not reveal a significant reduction in General Health Questionnaire scores. Third, even when the cutoff score was increased to 16, no significant findings emerged between localization of seizure focus and having a psychiatric disorder according to the General Health Questionnaire.

There are limitations to the conclusions that can be drawn from this study, however. The sample studied was selected and not representative of a general epilepsy population. The patients were treatment refractory and were admitted to a specialized unit for possible neurosurgical intervention. However, this study has the advantage of a large number of consecutive patients with a well-defined seizure focus. In the past, an apparent excess of temporal lobe epilepsy has been reported in psychiatrically abnormal patients with epilepsy. This study provides an opportunity to examine psychiatric morbidity in a large number of patients with focal epilepsy, both temporal and nontemporal.

Another limitation of this study is that the patients were not clinically evaluated but were assessed by using the General Health Questionnaire. This is because the study was essentially a pilot project to determine whether detailed psychiatric assessments are warranted in every candidate for epilepsy surgery (17). The General Health Questionnaire is essentially a screening test, but it does represent a general measure of nonpsychotic psychopathology in a medically ill population. Therefore, a conclusion that 45% of patients have psychiatric morbidity would at best be an approximation. However, it is also an indication for us to carry out detailed preoperative assessments on this group of patients.

All patients currently admitted to the epilepsy unit undergo a psychiatric diagnostic interview and standardized rating scale assessments to determine whether such data can predict postoperative emotional status and adjustments. The data from these evaluations will be forthcoming in the near future.

Neurobehavioral Functioning in a Nonconfounded Group of Asymptomatic HIV-Seropositive Homosexual Men

Robert A. Stern, Ph.D., Naomi G. Singer, B.A., Susan G. Silva, Ph.D.,
Helen J. Rogers, Ph.D., Diana O. Perkins, M.D., Colin D. Hall, M.D.,
Charles M. van der Horst, M.D., and Dwight L. Evans, M.D.

Neurobehavioral functioning was tested in 34 asymptomatic HIV-seropositive and 43 HIV-seronegative male homosexual subjects without substance abuse and CNS disorders. The HIV-positive subjects exhibited mild motor slowing compared to the seronegative subjects. These differences remained after controlling for potential cofactors. Early neurobehavioral impairment in HIV infection seems limited to subclinical motor deficits and attributable to HIV rather than possible confounding factors.

(Am J Psychiatry 1992; 149:1099-1102)

It is known that many patients with AIDS suffer from neurobehavioral dysfunction, including impairment of memory, language, information processing, attention, and motor function. While several reports have suggested that subclinical impairments may exist early in the course of HIV infection before other clinical signs and symptoms of AIDS appear (1-4), other investigators have not replicated these findings (5-7). Recent studies have suggested that if asymptomatic HIV-seropositive individuals exhibit neurobehavioral deficits, coexisting factors such as depression (8) or vitamin B₁₂ deficiency (9) may be the cause. Wilkins et al. (10) suggested that neurobehavioral impairment in asymptomatic HIV-positive persons may be due to confounding variables such as limited education or previous histories of substance abuse, learning disability, traumatic brain injury, or other CNS disorders. Furthermore, it has been suggested that immunosuppression precedes any neurobehavioral impairment (11).

The goals of this study were 1) to assess the impact of several potential coexisting factors on the early presentation of neurobehavioral impairments in HIV infec-

tion and 2) to examine these relationships in a group of subjects without confounding variables.

METHOD

The study was conducted as part of a larger investigation, the Coping in Health and Illness Project. The participants were 34 asymptomatic HIV-seropositive homosexual men and 43 HIV-seronegative homosexual male comparison subjects. Subjects were included if they were between the ages of 18 and 50 years, spoke English as their primary language, and had completed at least 10 years of schooling. HIV-positive subjects were included if homosexual contact was their sole risk factor for infection and if there were no clinical symptoms of immunosuppression. Strict exclusion criteria were used to preclude the confounding effects of substance abuse, mild head injury, learning disability, attention deficit disorder, or any preexisting CNS disorder (with the exception of occasional migraine headaches). Potential subjects were also excluded if they had ever taken zidovudine or if they had taken any medication other than acetaminophen during the 2 weeks before the study began. In addition, potential subjects were excluded if they had any significant past or present medical illness (e.g., heart disease, diabetes, endocrinopathies, autoimmune disorders, lung disease) or if they had undergone major surgery in the previous 6 months.

All potential subjects were administered a modified version of the Structured Clinical Interview for DSM-III-R (SCID) (12). Individuals with past or present psychotic disorders were excluded. Only five subjects not excluded on the basis of past or current nonpsychotic

axis I disorders fulfilled criteria for any psychiatric illness. These included one subject (2%) who was HIV negative and four (12%) who were HIV positive, all with major depression. (Specific exclusion criteria are available from the first author on request.)

The groups were similar in age (HIV positive, mean=30.1 years, SD=7.1; HIV negative, mean=32.2 years, SD=7.0), although the seronegative group had completed more years of schooling (HIV positive, mean=14.3, SD=2.5; HIV negative, mean=16.4, SD=2.2). All participants provided informed consent.

The subjects underwent a comprehensive neuropsychological evaluation. Following the guidelines of the National Institute of Mental Health Workshop on Neuropsychological Assessment Approaches (13), two experienced neuropsychologists (R.A.S. and H.J.R.) who were blind to the subjects' HIV status provided summary ratings for the following neurobehavioral domains: 1) attention and information processing, 2) executive function, 3) motor function, 4) language, 5) visuospatial function, and 6) learning and memory. In addition, a global impairment rating was given. Ratings were based on examination of raw test data, comparison of these data with published and internal norms, and written descriptions of behavioral observations. The two sets of ratings were averaged to create seven "function scores," each ranging from 1 (no impairment) to 9 (severe impairment).

Between-group differences were assessed first by analyses of variance and then by analyses of covariance. Covariates were education (years of schooling), socioeconomic status (Duncan's Revised Socioeconomic Index score [14]), depressive symptoms (score on the 17-item Hamilton Rating Scale for Depression), vitamin B₁₂ deficiency (plasma B₁₂ level), and immune status (CD4 cell count).

RESULTS

Without any covariates, the HIV-positive subjects performed significantly worse than HIV-negative sub-

jects on a variety of neuropsychological functions. With education covaried, significant group differences were found only on summary ratings of motor function and on individual motor function tests. This was expected because of the between-group differences in education level and the high correlations typically found between level of education and verbal skills (e.g., abstraction, naming, vocabulary, verbal memory).

The significant differences in motor function remained when each of the other covariates was controlled individually and when all covariates were included in the analyses simultaneously (tables 1 and 2). The differences observed on the 2 & 7 Test (a timed measure typically viewed as assessing selective attention) were due to the HIV-positive subjects' lower performance speed across conditions rather than attentional dysfunction (e.g., errors of omission).

DISCUSSION

In this group of asymptomatic HIV-positive homosexual men without the confounding factors of substance abuse, head injury, learning disability, zidovudine use, or preexisting CNS disorder, motor slowing was the only observed neurobehavioral deficit. It should be stressed that the motor dysfunction exhibited by these subjects was very mild and most likely would not affect their ability to carry out daily activities. There was no evidence of slowed information processing, memory impairment, or attentional dysfunction, as has been suggested by previous studies with more heterogeneous samples. The observed motor differences could not be accounted for by previously implicated factors such as education, socioeconomic status, depression, vitamin B₁₂ deficiency, or immune status. It is important to note that there were no significant group differences in Hamilton Depression Rating Scale scores, and neither group's mean score fell in the depressed range. Similarly, vitamin B₁₂ deficiency was infrequent (less than 10% of either group had levels less than 200 pg/ml). This may be due to the fact that our HIV-posi-

tive subjects were studied early in the course of HIV infection and met strict inclusion criteria. In a more heterogeneous group, these factors might have more influence on neuropsychological performance. These findings are based on a relatively small study group and therefore may not be generalizable to the larger population of HIV-infected individuals. Replication of these results in larger groups of subjects similarly lacking potentially confounding factors is necessary.

In summary, mild motor slowing may indicate CNS disturbance early in the course of HIV infection. This finding is consistent with recent reports of early CNS involvement in HIV. For example, cellular immunity has been found to diminish in the CNS before it does so in blood (15), and abnormalities in cerebrospinal fluid (16) and evoked potentials (17) have also been reported

in asymptomatic HIV-positive individuals. However, due to recent reports of peripheral nervous system involvement early in the course of HIV infection (18), further investigation of the underlying causes of HIV-related motor dysfunction is needed.

Nancy C. Andreasen, M.D., Ph.D., Editor

ETHICS AND LAW

Psychoanalysis and Ethics, by Ernest E. Wallwork. New Haven, Conn., Yale University Press, 1991, 344 pp., \$35.00.

Ernest Wallwork, a professor of ethics and a candidate in a psychoanalytic training institute, undertakes what might be considered a quixotic effort to at least modify the prevailing perception that psychoanalysis, with its bleak portrayal of the egoistic, narcissistic, and aggressive roots of human behavior, is an amoral discipline that allows no basis for either a philosophical or a practical theory of morality. In his preface, Wallwork promises an "accurate and sympathetic" reading of Freud that will justify a radical new interpretation of Freud and morality.

Wallwork is aware that his first task is to take a fresh look at the Freudian concepts of determinism, egoism, and narcissism, which stand as the primary roadblocks to his reevaluation. He begins by discussing the confusion in understanding Freud's writings engendered by the failure to take into account the differences between the metapsychological and clinical theories of psychoanalysis. Furthermore, neither professional philosophers nor psychoanalysts, for differing reasons, have expended much effort in trying to discern a philosophical basis for morality in Freud's writings. What of the apparent paradox derived from the conflict between Freud's alleged "hard" determinism and his assertion that the goal of psychoanalysis is to augment the freedom of the patient to make choices? Wallwork attempts to resolve this paradox by demonstrating that the psychic determinism of psychoanalysis, whose goal is to interpret clinical data, is not the same as the physical determinism of the sciences, which attempt causal explanations. Furthermore, unconscious motivations, although certainly very potent influences, especially when unacknowledged, are not the only determinants of human behavior, especially when the maturing ego gains some autonomy from their demands and sponsors a consequent growth of individual responsibility.

Wallwork then turns to psychological egoism, another of the preserved keystones of psychoanalytic amorality because, to the extent that individuals are under the domination of the pleasure principle, they attend only to their own self-interest and are incapable of any genuine concern for others. But the pleasure principle, leading to an unaltered psychological hedonism, is not the only factor influencing human behavior. It must give way partially to the reality principle, which at least allows the replacement of short-range by long-range satisfactions. Mature human goals extend toward happiness, of which pleasure is only a component, and this goal allows the interests of others to take their place along with self-satisfaction.

Wallwork answers the contention that we are so moved by narcissistic self-love that moral motivation is impossible by pointing out that narcissism is not limited to self-absorption and egoism but can also broaden to include self-love and self-regard. With maturation, and especially after the introduction

of eros in the second instinct theory, barriers to the existence of nonegoistic motives and love for others can at least be weakened. But we must still ask whether object love can be nonegoistic and other-regarding or whether this is impossible in the context of drive theory with self-satisfaction, immediate or delayed, as the only goal. As he does throughout the book, Wallwork answers this question by showing the progression in Freud's ideas and theories throughout his long career, especially after 1920 and "Beyond the Pleasure Principle" (1). Drives seeking only self-satisfaction can be transformed through aim inhibition and sublimation to form genuine other-regarding sentiments, providing room for the nonsensual elements of love alongside the sensual component. These allow the development not only of romantic love but also of group solidarity and social interests. Thus, it can be said that the relative benevolence of eros, while not eliminating egoistic instinctual demands, tempers and broadens love to include affectional elements in intimate relationships and benevolence and altruism in social relationships.

Is psychoanalysis of any value as a normative discipline with regard to ethical and moral standards? Freud disagreed violently with the "love commandment" that you should love your neighbor as yourself, asserting that it is impossible, unjust, indiscriminate, actually promotes hostility, and causes unhappiness. His arguments for these condign judgments are cogent, but Wallwork attempts to show that they are directed against a narrow interpretation of the love commandment (one may wonder whether Freud's hostility toward religion also played a role). Wallwork claims that Freudian doctrine may be quite compatible with a broader version of the love commandment that emphasizes nonmaleficence over a hypocritical universal love. Freud certainly would have preferred the doctrine of Hillel, not to do unto others what one would not like to have done to oneself, over the Golden Rule.

Can the allegedly value-free stance of psychoanalysis be compatible with an effort to use it for elucidating moral standards? Analysts take an avoidance of moral judgments as an article of faith and the only acceptable treatment posture. However, at least implicitly, psychoanalysis shares the values of science and of the healer, and analytic neutrality is not an end in itself but a device to encourage the patient's autonomy and freedom to choose. Also implicit in psychoanalytic technique are the moral rules of full disclosure, keeping promises, absence of sexual or other exploitation of the transference, and confidentiality. But even if psychoanalysis cannot avoid dealing with value judgments in its therapeutic endeavors, it still may be claimed that the discipline has nothing to contribute to the justification of these values. This is because of the relativistic implications of the superego, which asserts moral claims only on a basis of rewards and punishments, and the weakness of the ego, which is capable only of exerting an indirect bureaucratic power in finding somewhat more socially acceptable outlets for id desires. Wallwork responds to these contentions by denying that the ego is so weak or incapable of using rational grounds as a basis for moral decisions.

Freud was in vigorous favor of a rational and secular basis

for ethics and would not countenance any ontological grounds, either religious or philosophical, because moral principles must be generated from the human needs for happiness and love. He disagreed with Kant's assertion that reason and duty should be the only grounds for morality. Reason plays a part but must be balanced by human wishes, needs, and emotions. Although, rather surprisingly, Freud can be seen as holding the optimistic view that most people possess an other-regarding core as a basis for moral behavior, he had no doubts that this must be weighed against equally strong cruel and egoistic tendencies. The two opposing trends must contend with each other because "belief in the goodness of human nature is an evil illusion."

Can psychoanalysis identify the practical, personal reasons that should serve as normative guides to the way an individual should live in trying to achieve happiness, the ultimate good? Freud comes up with 11 paths to this goal. These paths are positive and negative and include both sexual and nonsensual modes. Possibly they can be summarized in Freud's succinct paradigm of "love and work."

Psychoanalysis, at least in Wallwork's reading of Freud, can contribute to the justification of moral principles from the social as well as the personal standpoint. Social rules are certainly necessary to protect against the ravages of naked instinctual urges, but they will be ineffective unless they are buttressed by the libidinal bonds of eros. Although the need to renounce aggressive and sexual satisfaction in the service of group aims inevitably constricts the possibilities for happiness (civilization must have its discontents), Freud offers a consolatory hope that the inevitable individual-versus-group conflicts can progressively be ameliorated by evolutionary developments. Meantime, a reasoned ethic for divided humans comprises the virtues of nonmaleficence, limited benevolence, honesty, promise keeping, autonomy, and justice. The criticism that for Freud justice is just a "mask for envy," a kind of dog in the manger ethic, may be answered by Freud's writings advocating the rule of law, equal treatment, liberty, distributive justice, and just war considerations even though adherence to these abstract principles will always be limited by man's animal heritage. Utopian hopes like communism will inevitably fail because of an erroneous view of human nature.

Much of the above can be summarized by stating that although man's instinctual egoistic core inevitably limits his ability to conform to "higher" and other-regarding principles, man is capable also of transcending the dominance of these elements by modifying their effects through aim inhibition and sublimation and through the influence of eros, which permits the possibility of altruistic behavior even at an instinctual level.

In *Psychoanalysis and Ethics*, Wallwork makes a formidable case for his position that Freud's views on morality and ethics are far more complicated and sophisticated than those attributed to him by his critics, and Wallwork seems to have succeeded in dispelling the notion that psychoanalysis is simply amoral and incapable of being used to explore the roots of ethics and morality. Wallwork accomplishes his purpose through a careful and even encyclopedic exegesis of what Freud said about the various subjects treated in the book. He repeatedly points out that Freud's critics, like Rieff, ignore statements by Freud that counterbalance the statements they quote. The salutary emphasis on how Freud's views changed during the evolving theoretical stages of his career serves as a corrective to simplistic views of Freud's theories.

Wallwork, I believe, has accomplished his purpose of "at least partially persuading" the reader to look at Freud, psy-

choanalysis, and morality in a different way. It seems clear, however, that Wallwork very much wants psychoanalysis to be freed from its burdensome reputation for amorality. Therefore, although he is by no means uncritical, his "sympathetic" attitude may raise questions about his objectivity. He perhaps neglects the point that even the apparent amorality of psychoanalysis has a moral effect when revelation of hidden motives deflate hypocritical moral pretensions. Wallwork appears totally accepting of Freudian clinical theories and findings, and he accepts as gospel such suspect theoretical entities as psychic energy. He also appears a bit naive in his infrequent references to clinical areas.

Psychoanalysis and Ethics is cogently reasoned and densely footnoted, even to the point of impeding the reading of this almost entirely abstract book. It is an impressive piece of work that may change the way Freud's concepts of morality are regarded. It will well repay the interest of those in the professional and intellectual world who take these matters seriously.

PAUL CHODOFF, M.D.
Washington, D.C.

Clinical Handbook of Psychiatry and the Law, 2nd ed., by Paul S. Appelbaum, M.D., and Thomas G. Gutheil, M.D. Baltimore, Williams & Wilkins, 1991, 408 pp., \$55.00.

The first edition of this excellent book was published in 1982. The authors have retained the format, the subjects covered, and much of the text material—wise decisions because they were so well presented and received. The book is geared toward clinical practice. The chapter subjects are confidentiality and privilege, legal issues in emergency psychiatry, legal issues in inpatient psychiatry, malpractice and other forms of liability, competence and substitute decision making, forensic evaluations, clinicians and lawyers, and the clinician in court. Each chapter is divided into seven sections: case examples, legal issues, clinical issues, pitfalls, case example epilogues, action guide, and suggested readings.

Here is a tip in reading this book. Resist the temptation to go directly from the cases to the epilogues. This generates considerable suspense, which makes for exciting reading, and the epilogues are more meaningful after the clinical and legal issues are clearly explicated.

There have been new developments since the 1982 edition. Gutheil and Appelbaum are now Appelbaum and Gutheil. The suggested readings have been substantially revised, enlarged, and brought up-to-date. Discussion of child custody has been eliminated; "readers are referred to one of the excellent texts available that now address the full range of child psychiatry and law issues."

Several new case vignettes have been added. There is one concerning a 28-year-old newly married man who is HIV positive, wants to have a child, but does not want to inform his wife of his HIV status. The ethical issues involved and the clinician's dilemma and its resolution are presented in the epilogue. This is the only reference to AIDS in this book, which is my one disappointment in this fine work. From where I sit, AIDS presents so many ethical and legal problems to psychia-

trists and other clinicians that I would have welcomed a fuller discussion of these overwhelming problems by such lucid and well-informed authors.

Recent court cases are cited. For instance, in discussing competence to consent to voluntary hospitalization, the authors comment that "a recent U.S. Supreme Court decision (*Zimmerman v. Burch*) may draw increased attention to this issue. The Court held that in those states, such as Florida, that require patients to be competent before signing in voluntarily, the failure to screen out incompetent patients violates these patients' constitutional rights. It is unclear whether the court would actually restrict voluntary hospitalization only to those patients found competent, assuming a state's statute is silent on the issue."

Important regulatory and legislative developments are also cited. In the chapter on malpractice and other forms of liability, the authors note,

In response to the perception that the professions have been ineffective in sanctioning sexual activity with patients, the states have become much more aggressive. Complaints to boards of registration routinely result in therapists losing their licenses. A growing number of states are passing laws requiring the reporting of sexual activity that becomes known to other health and mental health professions, and making it easier for patients to sue (e.g., defining the cause of action, extending the statute of limitations) and even criminalizing the behavior. Therapists found to have had sex with patients, and in some cases former patients, now face long prison terms in some states.

Some wording has also been improved since the first edition. In the chapter on the clinician in court, the authors in 1982 wrote about the "direct examination of the patient." In 1991 they substitute "the direct examination of the subject." This is surely more accurate because many individuals receiving forensic examinations are not "patients" in the generally accepted meaning of the term.

I highly recommend this book to all psychiatrists and other mental health practitioners. The many ways in which the law impinges on clinical practice are succinctly and brilliantly described. The methods by which the clinician can most effectively operate in these circumstances are clearly described and should be most helpful to all concerned.

HARVEY BLUESTONE, M.D.
Bronx, N.Y.

Alzheimer's Disease Research: Ethical and Legal Issues, edited by Joseph M. Berg, Harry Karlinsky, and Frederick H. Lowy. Toronto, Carswell, 1991, 354 pp., \$45.95 (C).

This work is the product of a symposium held in Toronto in 1989 on legal and ethical issues relating to Alzheimer's disease research. Unlike many symposium proceedings this work has been well edited and provides a balanced overview of legal and ethical issues relating to Alzheimer's disease research. Although the U.S. perspectives on legal issues are covered adequately, this book is clearly a Canadian product. Yet those of us who live south of the border would be wise to read how the Canadians approach these issues from their own perspective.

The work is divided into three main sections. First there is

a section on involving patients in research. Issues covered are primarily those of informed consent and alternatives to patients' giving consent themselves. Next there is a major effort devoted to ethical and legal issues arising from specific areas of Alzheimer's disease research. The general areas covered include etiological (including genetics), pathophysiological, diagnostic, and treatment-related research. The work concludes with a section on overall guidelines based on the current status of the field.

All in all I found this to be a worthy reference work that should be of use to those performing research in Alzheimer's disease, to those in the legal profession who define criteria for informed consent and other related issues, and to those on human subjects committees, who invariably will ask prospective Alzheimer's disease researchers the questions raised in this book.

JEROME A. YESAVAGE, M.D.
Palo Alto, Calif.

Decision Making in Psychiatry and the Law, by Thomas G. Gutheil, Harold J. Bursztajn, Archie Brodsky, and Victoria Alexander. Baltimore, Williams & Wilkins, 1991, 265 pp., \$36.00.

Just how are decisions about psychiatry made in the legal system? Dr. Gutheil and his colleagues at the Program in Psychiatry and the Law of the Massachusetts Mental Health Center and Harvard Medical School examine, by survey and interview, the factors that inform or produce a malpractice case involving suicide, the decision to commit a mentally ill patient involuntarily, the making of treatment decisions, and the determination of competence.

The malpractice case, based on an actual event, is designed as a heuristic exercise to highlight areas of decision making in psychiatry and the law. It is the opening chapter, and it reads like a novel, with dialogue setting out the risk-versus-benefit analysis of the situation. The doctor muses, "Will the patient be so dismayed by the experience of being involuntarily hospitalized that she despairs, resulting in an increased risk of suicide? Will 'taking over' for the patient intensify her feelings of helplessness?" And so forth. Thinking of all these possibilities, although stimulating for a seminar, may prompt the clinician to turn to a fortune cookie.

How do clinicians and judges weigh the risk and benefits of antipsychotic medications? How is the principle of triage (allocation of limited resources) used and misused in making decisions about "difficult" patients? Why do some patients decide to refuse treatment, and what are the clinical implications of validating or challenging treatment refusal? To answer these questions, the authors presented psychiatrists and judges (who were attending seminars on medicolegal issues) with clinical vignettes, asking them to assign weight to the risks and benefits.

As the authors point out, fantasies about treatment and the law and the wish for legally defensible procedures may lead to clinically inferior practices. Defensive medicine brings with it increased costs (but, when covered by insurance, it adds to income).

In commitment decisions, as every practitioner knows, psychiatrists tend to second-guess judges and judges tend to rely on psychiatric opinion. The authors call it "a type of role-switching." The authors' studies confirm that, in approaching commitment decisions, clinicians assume a judicial role by anticipating the judge's ruling on a case and judges assume a

clinical role by relying on the psychiatric evaluation and on extra-statutory factors concerned with compliance.

In dealing with treatment refusal, psychiatrists may feel "caught between torts." On one side are laws that protect patients against being treated against their will, and on the other side are laws that protect patients from negligence caused by lack of treatment.

Are psychiatrists and other physicians being literal-minded about the law? They have "respect for the law," which they tend to interpret to mean a literal reading of the law; hence, they question any tactical maneuvering in a case or any result-oriented decision. Persons labeled "schizophrenic" are known to be concrete in language and thought, but, curiously, psychiatrists on the whole seem to take a similar concrete-minded approach in interpreting rules of law.

Working from an interdisciplinary framework, the authors have produced a sophisticated and well-written book. They illustrate the various factors, subtle or otherwise, that go into the making of a decision. This is not a book for those who want firm and simple answers.

RALPH SLOVENKO, J.D., PH.D.
Detroit, Mich.

HISTORY OF PSYCHIATRY

Utopia, Community Care, and the Retreat From the Asylums, by Dylan Tomlinson. Philadelphia, Open University Press (New York, Taylor & Francis, distributor), 1991, 176 pp., \$70.00; \$29.95 (paper).

The reasons for closing state psychiatric hospitals in the United States is no grand mystery. States continue to shut down state beds and close state hospitals as a stratagem for shifting the fiscal burden of care of the patients from state government to the federal government (predominantly Medicaid and Medicare). Dylan Tomlinson's book is about the closing of public psychiatric hospitals in England, where the reasons for doing so are somewhat more complex even if the final product is equally as poorly thought through as the American version.

Tomlinson is a sociologist who worked with the Team for Assessment of Psychiatric Services evaluating what happened to 278 patients discharged between 1985 and 1988 from London's Friern and Claybury public psychiatric hospitals. Both hospitals were scheduled to be closed as part of the English trend in this direction; Barnstead, Powick, and Exeter hospitals had already been closed. For mental health professionals interested in this issue the book is worth obtaining for its details of the planning and politics that accompany such social service experiments. In Tomlinson's words, the hospital closings were predicated on "the revolutionary proposition . . . that all patients could live in community units outside asylums, and that their placements could be funded from the revenue sunk into the big hospitals" (p. 64). Probably never in the history of social services have such massive experiments been carried out with so little data or so little follow-up.

The Team for Assessment of Psychiatric Services was an effort to provide such follow-up, but methodologically it was quite unsatisfactory. The patients initially selected for discharge were those who were "more articulate and interested in moving" (p. 149), the best bets for community placement and thus not representative of all patients scheduled to be discharged. Furthermore, the team placed much emphasis on the

discharged patients' own statements that they did not wish to leave their group homes once placed there. Anyone who has worked with this patient population knows that many of them are very resistant to changes of venue and are likely to want to stay wherever they are at the time.

A true measure of what happens to these patients must take into account the number of their daily social contacts, opportunities for activities, opportunities for rehabilitation and work, and similar measures. There is no question that a large number of patients who have been deinstitutionalized from public psychiatric hospitals are better off than they were in the hospital, but this applies predominantly to the least impaired patients, such as this study encompasses. It is not at all clear that the more severely impaired, who have been merely "trans-institutionalized" to nursing homes or large, dreary group homes, are any better off, to say the least. What is probably most discouraging about this book is that England seems to be intent on replicating the worst, as well as the best, aspects of the American deinstitutionalization experiment.

E. FULLER TORREY, M.D.
Bethesda, Md.

Menninger: The Family and the Clinic, by Lawrence J. Friedman. New York, Alfred A. Knopf, 1990, 450 pp., \$29.95.

Lawrence Friedman, Professor of History and American Studies at Bowling Green State University in Ohio and a three-time recipient of fellowships from the National Endowment for the Humanities, has written a "triple-header" biography. First, this book concerns the individual as well as the family history of the Menningers, a distinguished family of psychiatrists now into the fourth generation of specialists in the field. Second, Professor Friedman gives us a slice of the history of American psychiatry during its critical and transitional years. Finally, we read about general American history of this specific time, particularly the changes that occurred in rural mid-America. With clarity and detail, and yet totally involving, the biographer presents us with facts, impressions, positive and negative issues that arose over the years, and in-depth portraits of key Menningers as well as the many nonfamily professionals who interacted with and were trained by the Menningers at the Clinic and the School and then moved to all parts of the United States and other countries.

The Menninger Clinic welcomed refugee colleagues who came here from Europe and helped them reestablish their personal and professional lives. Just as many came to Topeka, now the Clinic is establishing branches in other locations in the United States—migration goes in more than one direction. In many ways we find parallels between the Menninger institutions and programs and those organized and operated by the Mayo Clinic.

Having had the privilege of knowing members of the last three Menninger generations as well as many others who were educated and trained in Topeka, I can attest to the dedication, honesty, excellent clinical care, and path-breaking research that is associated with the Menninger Clinic, School, and Foundation.

Professor Friedman highlights details of the frontier areas discovered by the Menninger immediate and extended family, as well as other pioneers of the time, and includes the support given to other disciplines involved with mental health and illness. Through access to archives, private papers, personal interviews, and government reports, the reader gains an appreciation of "the influence of family dynamics upon institutional

activities" in the years before World War II and how during the subsequent decades the institution expanded and formally became a nonprofit foundation devoted to education, research, publications, and clinical activities. The author's emphasis is on the evolution and connections between the early family members and the organization that has emerged and continues to keep pace with the major advances in the mental health field.

Professor Friedman began the research that resulted in this excellent volume in 1981, when he came to Topeka to participate in the Menninger Interdisciplinary Studies Program. He was formally given permission to "see all" in March 1982. Patient records and diagnostic data were "off bounds," but he was given access to organizational and personal files, including letters and documents. "Karl honored my request to reveal everything that was relevant to my narrative" (p. xiv). "The openness of the Menningers . . . was courageous. They knew that serious scandals and other shortcomings in their history would be presented and that public awareness of these details might affect patient referrals, staff recruitment, and private donations" (p. xiv). This has not occurred. In fact, as testimony to the very professional ethics and ideals that exemplify the Menninger institutions, this book has and will add to their already gigantic stature and reputation.

The "scholar's dream" was not one-sided—methodological dilemmas presented themselves. Professor Friedman, I believe, has successfully dealt with these. He fulfilled his scholar's dream by carefully obtaining an overwhelming amount of information. He traveled to or corresponded with other institutions, talked with dozens of individuals who candidly shared their information and impressions with him, was allowed to read heretofore sealed documents, and received countless telephone messages. We can read in this condensed but flowing narrative a synthesis of newer methodological approaches to historical and biographical research. The processing of the information and then the clear, lucid presentation of what the historian-biographer has learned resembles the approach the psychoanalyst uses with data obtained in the treatment setting. Professor Friedman correctly states, "This was a very difficult book to research and to write" (p. xvii), but he did it in exemplary fashion. It will be a model for future reports of the history of institutions and the biography of individuals worthy of the efforts and work seen in this book.

I have refrained from giving details, simple and complex, about the contents of the book. The time and energy of the interested reader will be amply rewarded. The careful notes (almost 100 pages in length), the bibliographical notes, and the excellent index enhance the value of an already very valuable piece of work.

The Menninger institution continues to grow, expand, and develop. In a recent issue of the *Menninger Perspective*, Glen Gabbard, M.D., Vice-President for Adult Services of the Menninger Clinic and Director of the C.F. Menninger Memorial Hospital, reported that the Menninger organization now has "more than 1,200 employees on two campuses in Topeka and in satellite clinics in San Francisco, Phoenix, Tampa, and Kansas City" (1). In this same issue, the new organizational structure was announced (2). Dr. Roy Menninger, son of Dr. Will, is President and Chief Executive Officer of the parent Menninger Foundation. His brother, Dr. W. Walter Menninger, is the President and Chief of Staff of the Menninger Clinic. Thus, two Menninger brothers again head the institution that was started and developed by two earlier Menninger brothers, Dr. Karl and Dr. Will. In a sense, we are having durable continuities in a major American institution.

GEORGE H. POLLOCK, M.D., PH.D.
Chicago, Ill.

PERSONALITY

Psychobiology of Personality, by Marvin Zuckerman. New York, Cambridge University Press, 1991, 400 pp., \$65.00; \$29.95 (paper).

This is a useful book. It presents an up-to-date review of thinking and research dealing with personality, primarily from a psychobiological point of view. It is part of a series entitled *Problems in the Behavioral Sciences*, edited by Jeffrey Gray.

The author's preface begins with the following interesting description of his orientation:

It is not by a natural intellectual progression that one begins as a clinical psychologist in the 1950s during the era of psychoanalytic and social-environmental theory, and ends by writing a book 40 years later on the "psychobiology of personality." The first stage of evolution was an increasing skepticism of dynamic post hoc explanations of personality during my early career as a full-time clinical psychologist. Not only the study of patients, but observations of my own developing children raised questions about the adequacy of environmental explanation alone. What father can remain an adamant environmentalist after he has his second child?

The author's strategic thinking is set forth in another quotation from the first page of the text:

Sciences need systems for classifying their phenomena whether these are astronomical objects, units of matter, or species of animals. A science of astronomy that made no distinctions among planets, stars, and galaxies, a geology that regarded every rock as a unique structure, or a biology that could only distinguish two-legged from four-legged creatures, would not progress very far in understanding or prediction. Without a classification of species there could have been no *On the Origin of Species*.

The author then goes on to present a clear and satisfactory review of the literature. The chapter titles include "Basic Dimensions of Personality," "Consistency of Personality," "Behavioral Genetics and Personality Traits," "Neuropsychology," "Psychopharmacology," "Psychophysiology," "Learning," "Anxiety Disorders," "Antisocial Personality and Other Disinhibitory Disorders," and "Measures and Models, Problems and Progress." The list of references is extensive and apparently up-to-date. In addition, the author presents useful tables and figures in which he summarizes much of the important data he writes about.

I think the book could be useful as a textbook for psychol-

ogy graduate students, and a good deal of it will be of interest to psychiatry residents as well as practicing psychiatrists.

I have one specific suggestion for improving the book if it is ever revised. It would be very helpful to expand the table of contents so that the subsections of the individual chapters are listed.

Reading through the book provides the reader with a broad grasp of the field as well as an understanding of some of the important conceptual and methodological problems inherent in much of the research described.

EATING DISORDERS

Special Problems in Managing Eating Disorders, edited by Joel Yager, M.D., Harry E. Gwirtsman, M.D., and Carole K. Edelstein, M.D. Washington, D.C., American Psychiatric Press, 1992, 237 pp., \$29.95.

Ten years ago, bulimia nervosa had just been recognized by *DSM-III*, and virtually no data were available on the management of this disorder in clinical practice or on the efficacy of specific treatment modalities. Even the more venerable literature on anorexia nervosa contained only a few rigorous studies of treatment; indeed, one analysis at that time noted that there had been no appreciable improvement in the prognosis of anorexia nervosa in the 50-year period from 1931 to 1981.

Since 1981, however, an explosion of studies has filled the literature with extensive data on the treatment of eating disorders and the many disorders that appear to occur comorbidly with them. Already this literature has become far too extensive for all but the specialist to follow. Thus, Yager, Gwirtsman, and Edelstein have performed a valuable service by attempting to condense much of this information into a small volume specifically designed to offer concrete help to the practicing clinician.

Most of the book's chapters address the numerous conditions that may occur comorbidly with eating disorders. These include psychiatric disorders, such as substance abuse, major mood disorders, and personality disorders; independent medical conditions, such as pregnancy and diabetes mellitus; and medical complications of the eating disorders themselves, including problems brought on by the abuse of laxatives and emetics. In each of these areas, the contributors not only assemble the available literature but also provide extensive case examples from their own practices to illustrate practical problems encountered in actual clinical situations. Despite the delays often inherent in assembling a multi-authored book of this type, the chapters all manage to be quite up-to-date in their coverage of the literature—an important attribute in a field with such a rapid expansion of knowledge.

I particularly recommend several chapters that assemble in a single place material rarely so well summarized before. For example, Arnold Andersen's piece on males with eating disorders is a particularly useful overview of this special topic. The chapter on laxative and emetic abuse brings together more information on this important aspect of eating disorders than I have previously seen in one place. And the final chapter, on the management of chronic and recalcitrant cases of eating disorders, provides guidelines in an area that is too rarely addressed.

In short, clinicians who regularly treat patients with eating

disorders will find this an invaluable reference. In 2 or 3 hours of reading they will gain an overview of a massive and rapidly growing literature as well as concrete, useful information on how to handle their patients.

PSYCHE AND SOMA

Current Concepts of Somatization, edited by Laurence J. Kirmayer, M.D., F.R.C.P.(C), and James M. Robbins, Ph.D. Washington, D.C., American Psychiatric Press, 1991, 225 pp., \$31.50.

Somatization may be defined as the phenomenon by which psychological distress is expressed in somatic language and behavior and, as such, serves in many cultures as the predominant mode of affective communication. The complex process by which affective distress is communicated in somatic terms may be influenced by a multiplicity of genetic, cultural, developmental, interpersonal, and cognitive factors, and this volume examines the phenomenon of somatization from a variety of perspectives. Although a unitary theory to explain somatization is not yet possible, the editors provide multiple viewpoints on the subject and attempt to integrate them where possible. For example, from the standpoint of cognitive psychology, Pennebaker and Watson discuss the role of perception and selective attention to somatic stimuli in individual differences in reporting dysphoric states. Gregory Simon examines the relationship between somatization and the burden it places on health care utilization. He uses the population-based epidemiologic approach derived from the National Institute of Mental Health Epidemiologic Catchment Area project to analyze clusters of somatic symptoms in community samples and argues that patterns of somatization are common in the general community and only a relatively small percentage of subjects fall within the framework of what would traditionally be considered psychopathological. Other chapters review the relationship between somatization and anxiety and depression (including "masked" forms of psychiatric illness) and manifestations of somatization in primary care settings. Ford and Parker review the clinical aspects of somatization in consultation-liaison settings, particularly the role of medical-psychiatric units in the treatment of somatization-spectrum disorders. Although Kellner specifically addresses the literature on treatment, it becomes readily apparent that evaluating the efficacy of reported interventions for somatization syndromes is confounded by the lack of controlled studies as well as the lack of standardized diagnostic criteria for subject selection. The more or less "discrete," relatively common somatic syndromes encountered at the medical-psychiatric interface (fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome) are also examined in an excellent and comprehensive review by the editors.

If the text has a weakness, it may be the lack of an extensive discussion of developmental affective psycholinguistics, that is, the process by which the words of somatic language (somatothymic language) are differentiated into more abstract psychological word-symbols by cultural, developmental, familial, and learning factors. In this regard, the concept of alexithymia is given insufficient attention. Discussion of Kleinman's classic anthropological work on somatization could

also have been expanded, particularly his landmark study of neurasthenia in China.

This text provides a compact review of clinical and research aspects of the phenomenon of somatization. It is the best consolidation of the available literature since Charles Ford's *The Somatizing Disorders* (1). As a concise and timely review of the available literature, *Current Concepts of Somatization* serves its purpose well in providing a multidimensional approach to the subject that should be useful to clinicians in both medicine and psychiatry who are interested in the various forms and transformations of somatization in human behavior.

ALAN STOUDEMIRE, M.D.
Atlanta, Ga.

From Paralysis to Fatigue: A History of Psychosomatic Illness in the Modern Era, by Edward Shorter. New York, Free Press, 1991, 419 pp., \$24.95.

This is a history of imaginary sickness written by a historian of medicine. It details the vicissitudes of somatic manifestations of psychological disequilibrium from the late nineteenth century into the present with occasional more antique references to the sixteenth and seventeenth centuries. A substantial part of the text consists of vignettes otherwise not easily accessible, translated from original sources. These vignettes can be of great value as historical referents for teaching on somatiform and psychosomatic illness.

The book is divided into large sections that chronicle the changes in the ways psychogenic sickness was, and is, manifested. The author presents his view of the changing prevalent ideas of what "facts" dictate diagnosis and treatment. The book starts with addressing the phenomenon of "psychogenic symptoms" and the nineteenth-century views of illness. The author clearly wishes to acquaint the uninitiated regarding the existence and "strength" of the unconscious force. Each chapter addresses within a temporal framework the historic ideas regarding the mysterious origins of what Freud called the "leap." Two chapters describe nineteenth-century somatic views, involving "spinal irritation" and a related but different view regarding "reflex theory." Both of these "theories" were directed toward symptoms emerging from some predisposition of the nervous system or the affected organ. The author states that such etiologies provided a "face saving fig leaf . . . for [hysterical manifestations], so that it is almost a shame [such diagnoses] were discredited." This somewhat confused metaphor conveys a pervasive view of the author—that although the origin for such illness manifestation did not belong exclusively within the body space, the later general acceptance of psychoanalytic ideas regarding etiology shamed the somatizing patient. Patients find somatic explanation for somatic difficulties far more acceptable, even if the price paid is surgical mutilation.

Such a surgical approach, as espoused by physicians for cure of, for example, "pelvic madness," led to "Battey's operation" (ovariotomy) for "nymphomania" and "hystero-epilepsy." Such "Battey-izing" and other "gynecologic tinkering" continued until late into the nineteenth century. (We know, also, that it certainly has continued in different guise even into the

present.) Women frequently asked for removal of their ovaries or clitoris (the latter by surgery or cautery or caustics) as cure for excessive sexual preoccupations or "irritability." So severe was the implicit general moral sanction and deprecation of women that the desire for such surgery by some women was also to be viewed as a psychosomatic symptom. Nor did psychiatrists at that time help. Many of the psychiatrists urged the use of gynecology in the asylums "primarily on the ground that the insane woman has as much right to be treated for bodily disease . . . as her sane sister." This was the usual conflating of seeming moral concern for the "weak" with their subjugation. This is also a contemporary battle; current views often politically and legally place one sex in the position of the inferior (1). We are told that Charcot's student Georges Gilles de la Tourette labeled such operations as "absolutely wrong."

Subsequent chapters trace the rise of motor hysteria (or hysterical paralysis) and dissociation and related phenomena, with surprising information on the frequency of catalepsy and somnambulism. Charcot is fittingly accorded a chapter with interesting biographical information and gossip on his life. It is noted that Charcot believed in somatic origins for *la grande hystérie* early and only later in life saw it as *maladie mentale*.

Later chapters encounter the gradual shift toward the concept of a cause for nervous disease in the nervous system, starting with central theories for neurosis and psychosis. The forerunner of a "psychologic paradigm" was seen in the 1880s, although earlier commentators on the human condition had made such statements far back in human history. (Epictetus announced centuries before that humankind's fantasies "alarm and disturb" more than the facts.) Psychotherapies for somatizing patients often included solace and acknowledgment of the patient's burden accompanied by placebo—as if there were, in fact, a somatic origin for the somatic symptom. Psychoanalysis is, in contrast, presented as oppression, not quite equal to that imposed by gynecologists for the same ailments. Psychoanalysts are presented as "hijacking the psychotherapies . . . [and grabbing] control of the other budding psychotherapies," and, for patients, "instilling a horror at the prospects of psychotherapy."

The important contemporary symptoms of neuromyasthenia (later called "chronic fatigue syndrome") and the Epstein-Barr virus as etiologic are addressed. The specialized reader will not find much in the way of clinically relevant summaries but more about shifting ideas and the personalities involved. The author is a historian, not a physician, and it is best to approach this volume with that understanding. The clinical specialist in this field may otherwise experience some impatience. The index is weak, omitting important entries that are in the text (S. Weir Mitchell, for example). There are phrases intended for the reader with only rudimentary medical knowledge (here is one small example: "bacteria" as the cause of syphilis rather than *Spirochaeta*). There is a lack of textured differentiation and also contradictions to what psychiatrists understand about somatic presentations. There is no reference to *DSM-III*. Psychoanalysis is deeply criticized with what seems like a superficial presentation of its theory, technique, intent, and change with time. There are places where concepts (for example, the unconscious) are reified or treated in a way that is too simplified for those of us who use the ideas as a second nature: "Given the reluctance of the unconscious to be made a fool of, patients have always tended to reject psychological interpretations of physical symptoms." Psychiatrists usually do not talk that way, at least to each other. When we read on those subjects we know about, we expect a large synthesis, new data, or a novel way of looking at things. The novelty of this book, for psychiatrists, is that it presents pri-

marily a historical, not a clinical, nosologic framework. Physicians can make best use of it by suspending some critical judgment.

This book presents more a developmental synthesis of cultural ideas regarding an important aspect of diversity surrounding sickness than a history of psychiatric treatment. Shorter keeps a fine edge on his criticism of the injustice visited on the patient by society and more proximally by the doctor. Although past and current physicians are not uniformly ignorant, venal, or brutal, this history reminds us that our actions individually and collectively can be so categorized. We can learn or, better, continuously relearn to shun a sense of absolute certainty and to cherish our tolerance for ambiguity as our natural state. Toward that purpose this scholarly historical reprise is valuable. And even if we care little about history's judgment we do care about our patients.

CHILDREN

Children With Conduct Disorders: A Psychotherapy Manual, by Paulina Kernberg and Saralea E. Chazan. New York, Basic Books, 1991, 297 pp., \$27.95.

The focus of this book is on the treatment of children with conduct and oppositional disorders. The book is designed to provide a treatment manual that will be of use to both clinicians and researchers. The conceptual framework draws primarily on ego analytic, object relations theory supplemented by concepts drawn from attachment, temperament, learning, and group dynamic approaches.

The book is organized into three parts covering three separate but interrelated therapy techniques. The treatments address significant influences that contribute to conduct disorder and disruptive behavior, namely, processes within the child, parent-child interactions, and peer processes and relations. The three treatments are supportive-expressive play therapy, parent training, and play group therapy. Each therapy is described with its own chapters that cover separate phases (initiation, continuation, and termination) of treatment. For each phase of treatment, fundamental processes and specific strategies are described. How the principles and strategies are to be applied concretely are well illustrated with sample therapist statements, dialogue and interchanges with patients, and case material. Thus, the book at once integrates theory and practice in a way that is clear, well organized, and thoughtfully presented.

The virtues of the book can be better seen in the context of child and adolescent psychotherapy more generally. The vast majority of psychotherapy techniques for children and adolescents currently in use (more than 230) have never been subjected to empirical research (1). Regrettably, the path from development of treatment to use and dissemination of psychotherapy does not require investigation. In the development of treatment, a critical element is specification of treatment in such a way that key elements are made explicit so that the treatment can be evaluated. Several treatment manuals are

now available for child and adolescent therapies involving psychodynamic, psychoanalytic, behavior, cognitive, and family therapies. This book adds to the store of available treatment manuals. Development of treatment manuals is not an end in itself. Rather, this is a step toward evaluation and clinical trials of the effectiveness and bases of treatment. The present book is rich in delineating procedures, strategies, and processes that can be subject to empirical test. It remains for our field to test the claims directly. In advance of the data, the authors are to be credited with moving supportive therapy, parent training, and play group therapy closer to the empirical arena.

Some weaknesses can be identified. Assessment methods to decide what treatment to provide to whom, how to evaluate whether therapeutic change has occurred to address psychodynamic conflicts central to each approach, and how to assess the processes thought to carry the burden of therapeutic change are not covered. These weaknesses are significant in relation to the next step for research but worth deemphasizing in deference to the contribution represented by the "manualization" of the treatments in this book.

Clinical Guide to Depression in Children and Adolescents, edited by Mohammad Shafii, M.D., and Sharon Lee Shafii, R.N., B.S.N. Washington, D.C., American Psychiatric Press, 1992, 294 pp., \$38.00.

The appearance of this multi-authored book on the clinical management and treatment of depression in children and adolescents should be viewed against a historical background. Just two decades ago, the conventional belief was that children did not get depressed or, if they did, it was masked. Epidemiologic studies of adults have consistently demonstrated that the average age at first onset of depression is often in adolescence, that prepubertal onset of depression, although infrequent, does occur, and that there has been an increase in the rates of depression worldwide in study groups born since World War II and that the average age at onset has decreased. Clinical studies show that depression in children and adolescents is associated with high morbidity. Although the last decade has witnessed an increasing amount of systematic research on depression in children and adolescents, the empirical basis for treatment is far behind that of adult depression.

This book attempts to collect the most current research on the epidemiology, neurobiology, phenomenology, and treatment of depression of children and adolescents and to present it in a form that is of use to the clinician. Due to the paucity of information, the authors have often had to extrapolate from studies of depressed adults. A revision of this book will be needed in several years to include more recent studies of the offspring of depressed parents, the adaptations of short-term adult psychotherapies to the treatment of adolescents, and the studies of depressed children who have grown up. In the meantime, this is an excellent review, written in a readable but well-referenced fashion, that should be of use to clinicians as well as new investigators wanting to learn about the field.

The chapter on the pharmacological treatment of depres-

sion is particularly useful. It summarizes the primarily negative studies so far, discusses the methodologic problems, and gives a reasonable clinical guide to the use of pharmacotherapy. The two chapters on individual psychotherapy, dynamic psychotherapy, and cognitive therapy need to rely on clinical experience alone because there had not been any published controlled clinical trials of any individual psychotherapy in depressed children or adolescents. Fortunately, manuals are being developed for cognitive and interpersonal psychotherapy, and studies are in the planning phases. There have been some recent trials on group approaches to the treatment of depressed adolescents, but these are not included in the chapter on group psychotherapy. A future revision of this book will definitely be needed in this area in a few years. The chapters on bipolar disorder are excellent synopses of the state of understanding done by investigators who are active researchers in this area.

In summary, this is a well-written, useful, and, for the most part, empirically based clinical guide in an area of public health importance.

FREUDIAN CLASSICS

On Freud's "Analysis Terminable and Interminable," edited by Joseph Sandler, Ethel Spector Person, and Peter Fonagy for the International Psychoanalytical Association. New Haven, Conn., Yale University Press, 1991, 162 pp., \$22.50.

This slender volume represents the first in a new series entitled Contemporary Freud: Turning Points and Critical Issues, which proposes in each volume to present one of Freud's classic papers followed by commentary by a number of psychoanalysts from different countries and with different theoretical perspectives. (I have already read the second book in this series, which deals with "On Narcissism: An Introduction" [1], and can attest that it is wonderful.) The present volume, which is not quite as illuminating as the second volume in the series, concerns the masterpiece "Analysis Terminable and Interminable," published in 1937 when Freud was 81 years old, a truly remarkable work by a man of any age, and made more remarkable by the advanced age of its author.

Years ago, one could assume that everyone reading this review would be familiar with this famous paper, but I regret to say that, as a function of the change in what is taught in psychiatric residency programs today, this assumption can no longer be made. To anyone who is interested in doing psychotherapy, this paper by Freud is an absolute classic and required for reading and study. It has many highly controversial statements and has often been called pessimistic, but it is remarkable for its calm and clearheaded realism and for its prescience in raising a number of issues that became increasingly important after Freud's death.

Somewhat loosely organized, Freud's paper purports to be a clinical study but actually contains many overt and covert controversial metapsychological assumptions. It deals primarily with the limitations of psychoanalysis. The editors tell us that, for Freud, "the outcome of treatment is ultimately constricted by 1) the constitutionally determined intensity of the patient's drives, 2) the severity of infantile traumas, and 3) the degree of ego distortion produced by defenses" (p. x). Among these resistances to recovery, Freud discussed certain "altera-

tions" in the ego that in turn are selected on the basis of factors determined by inherited and cultural dispositions. These alterations are effects brought about in the ego by the defenses and by certain constitutional factors, such as adhesiveness of the libido, too mobile a libido, depletion of plasticity and capacity for change, and an ultimate force toward suffering involving guilt, the need for punishment, and the death instinct. Some of these metapsychological concepts are outmoded today, and the paper includes a somewhat difficult mixture of Freud's topographic and structural theories.

Freud also focuses on the analyst and his or her role in the success or failure of the treatment. He points out that analysts do not always come up to par as models of normality, teachers, and persons with a love of truth that "precludes any kind of sham or deceit" (p. 35). This leads to Freud's famous statement that psychoanalysis along with education and government is an "impossible" profession.

The discussions in the volume range over a wide area of topics, some of which are quite abstruse, and in the present review I will touch on only some points that may be of interest to psychiatrists. Arlow points out the inconsistencies in the two models used in the paper: "Whereas the topographic model stressed the pathogenic significance of what was repressed into the system *Ucs*, the structural model stressed the role of intrapsychic conflict and compromise formation" (p. 43). Arlow points out that undoing repression, for example by recollecting forgotten memories, is no longer the crucial aim of psychoanalytic technique, although Freud in this essay concentrated on it as crucial. Arlow offers an update of Freud's approach in the light of ego psychology and the structural theory as well as some of his own ideas about unconscious fantasies. Thus, the analysis of compromise formations, especially those which are ineffective and pathogenic, becomes the central technical issue rather than the uncovering of the repressed. Arlow offers a number of other emendations and corrections of Freud's paper without detracting from the greatness of this classic work. To those interested in the whole topic of how psychoanalytic treatment works, Arlow's commentary is required reading along with Freud's paper, as long as one remembers that some of Arlow's contentions also remain controversial.

The volume would have been improved if Arlow's "traditional" paper had been followed by a discussion written by a self psychologist such as Muslin (2). However, I fear that some psychiatrists will become lost in at least a little of the published discussion that actually follows in the volume, because it becomes at times quite abstruse and occasionally assumes some highly technical theoretical knowledge of metapsychology and of disagreements at a metapsychological level among psychoanalysts. There is also considerable discussion of historical detail surrounding the composition of this paper, which may be of interest but is not of primarily practical importance.

There are some further useful emendations, however. Zimmermann and Mostardeiro divide Freud's paper up by the topics covered and comment lucidly and in a clinical manner on each. These topics include the duration of the analysis, assessing the readiness to terminate, the constitutional strength of the drives, protection against further psychic conflict, alterations in ego structure, the personality of the analyst, and issues involving femininity. In general, Zimmermann and Mostardeiro seem more accepting of Freud's position than Arlow, and their conclusions (pp. 90-91) have valuable clinical content and should be studied carefully.

A Kleinian discussion of some of the subthemes of the paper is offered by de Folch. Cooper wisely challenges what is probably the weakest part of Freud's paper, namely, his notions of

masculinity, femininity, and of what constitutes the "bed-rock" of analysis. Very few analysts agree with Freud's views on these topics today.

The remarkably wide range of the discussions stirred up by Freud's paper illustrates its fertility and importance to anyone who would practice psychotherapy. For those who are not familiar with Freud's paper, this book is an excellent starting point because it begins with a reprint of the paper. For those who are familiar with the paper, there is something for every kind of interest in the discussions that follow it, and I can recommend the book highly. The primary audience for this book are psychoanalysts, and those psychiatrists who are not psychoanalytically oriented will not appreciate the topics covered in it. I have discussed my own views on some of these issues elsewhere (3, 4), and the *International Journal of Psycho-Analysis*, volume 68, part 1, 1987, contains three more papers on Freud's classic that should be read along with this book.

RICHARD D. CHESSICK, M.D., PH.D.
Evanston, Ill.

Freud's "On Narcissism: An Introduction," edited by Joseph Sandler, Ethel Spector Person, and Peter Fonagy for the International Psychoanalytical Association. New Haven, Conn., Yale University Press, 1991, 227 pp., \$27.50.

Almost 80 years have passed since Sigmund Freud introduced the term "narcissism" into the language of psychiatry, transforming it from the designation of an obscure sexual deviation to a broad general concept with major implications for theories of normal development, psychopathology, and psychoanalytic therapy. Like many of his landmark essays, "On Narcissism: An Introduction," published in 1914, has been reconsidered and reinterpreted repeatedly as psychoanalytic theory has evolved and has been applied to a broad range of clinical problems and issues in the social sciences (e.g.,

Christopher Lasch's *The Culture of Narcissism* [1]). Many readers have found the paper heavy going; in covering so broad a terrain it left many stones unturned and boundaries uncertain.

As one of its continuing series of volumes on Contemporary Freud: Turning Points and Critical Issues, the International Psychoanalytical Association has organized this symposium, opening with a reprinting of Freud's essay and following it with a set of commentaries, critiques, and updatings by an international group of psychoanalysts representing the spectrum of current viewpoints within the widening mainstream of analysis in the 1990s.

Clifford Yorke's "teaching text" is particularly valuable in pointing up the areas of semantic unclarity and conceptual transition that mark Freud's attempt to bring his new clinical observations into line with the increasingly shaky edifice of the libido theory, then under assault by Adler and Jung. Otto Kernberg offers a "contemporary reading," presenting in brief his effort to synthesize an object relations perspective with traditional drive theory, and Paul Ornstein presents a lucid distillation and defense of Kohut's revisionist views that, emerging from his observations of narcissistic transference, have evolved into a "self psychology" which challenges classical conflict theory. Hannah Segal and David Bell contribute a particularly clear statement of the contemporary Kleinian viewpoint, challenging Freud's notion of "primary narcissism" in favor of the thesis that object relations are present from the moment of birth. Indeed, Bela Grunberger, a French analyst, would trace psychic life to the intrauterine period and considers narcissistic phenomena to be regressive expressions of—at least fleeting—unconscious memories of fetal life.

Other contributors, less known to American psychiatric readers, bring perspectives from European and Latin American psychoanalysis that enlarge upon but do not fundamentally conflict with these more familiar views. Together they develop a wide-ranging exegesis of a complex problem that Freud bequeathed to posterity with this provocative but often puzzling paper. The editors have performed a valuable service by underscoring the epistemological and clinical issues that Freud left unresolved and by bringing together a group of thoughtful efforts to engage and clarify them. For those who have long struggled with "On Narcissism," this volume may prove a useful guide to the perplexed.

Sudden Self-Harm While Taking Fluoxetine

SIR: We would like to report a case in which a patient taking fluoxetine was suddenly overcome by the urge to do himself harm.

Mr. A, a 44-year-old man with chronic depression, mixed symptoms, was treated in a double-blind trial of nefazodone, fluoxetine, or placebo. Clinical features included sadness, dysphoria, and repressed irritability; some compulsive counting, showering, and cleaning; and passive suicidal ideation. These features showed a mild seasonal pattern. He kept to himself to preclude arguments or lashing out. His occupational performance was unimpaired by depression, but his social life was significantly curtailed. His wife said he was verbally, but not physically, abusive to his children.

Mr. A had abused alcohol 25 years earlier during a previous episode of depression; he experienced limited symptom anxiety attacks during the current episode. Alcoholism was present in both maternal and paternal relatives, a paternal aunt committed suicide, and a paternal uncle was "psychotic." His childhood history revealed poor concentration, nervousness, inattention, shyness, impersistence, and dyslexia and "learning disabilities." Thus, he may have suffered attention deficit disorder in childhood. Although he was physically abused by his father as a child, he had no documented history of head injury or neurologic disease.

On a previous trial of fluoxetine, 60 mg/day, he noted better mood, followed by irritability, mood lability, and other symptoms consistent with either mild hypomania or agitation. His previous irritable and abusive behavior was probably symptomatic of a mixed mood disorder rather than borderline personality disorder.

Mr. A failed to respond to an 8-week trial of what was later identified as nefazodone and was crossed over to what was later identified as fluoxetine. He responded partially (17-item Hamilton Rating Scale for Depression score decreased from 24 to 10) after 10 weeks on a regimen of fluoxetine, 40 mg/day. At 12 weeks he felt mounting tension and an increase in depressive symptoms following subjective work stress. We assumed lack of efficacy and increased the dose to three capsules (later identified as fluoxetine, 60 mg/day). The patient mistakenly increased the dose to 80 mg/day. Twenty-four hours after the 80-mg dose, he impulsively made superficial cuts to his throat, wrist, and abdomen while driving, with the express purpose of cutting but not killing himself. This compulsion was accompanied by relief but not pain. He had never had the urge to cut himself before. Within 48 hours (160-mg additional dose), he suffered disturbing nightmares, best remembered as "I'm being hurt."

The patient decreased the dose to 20 mg/day. Within 24 hours the urge to cut himself had disappeared, and within 48 hours the disturbing nightmares had stopped. After 1 week of 20 mg/day dosing he noted clear loss of drug efficacy (17-item Hamilton depression scale score was 16), and the research trial was terminated. The code was broken and

study drug number 2 was identified as fluoxetine. The adverse events appeared directly related to the dose of the study drug.

Desipramine, 150 mg/day, led to a significant decrease in depressive symptoms, but no return of nightmares or urge to cut himself. Mr. A's sour disposition and irritability remained.

Like many of the original cases reported by Teicher et al. (1), this man may have had a CNS abnormality. No EEG or imaging studies were performed. Downs et al. (2) have suggested that "obsessive-like, violent thoughts of suicide will occur in patients with some form of limbic system dysfunction." This case demonstrates a prior possible hypomanic response to fluoxetine (3) and a dose-related, irresistible impulse to cut but not kill oneself. The sudden urge to cut appears related to dose but not antidepressant effect, so it may be due to an intolerable agitation rather than a switch to mania.

Fluoxetine-Induced Anorexia in a Bulimic Patient

SIR: Fluoxetine treatment for bulimia nervosa has been recently reviewed, suggesting its efficacy in this eating disorder (1). We report a case of a bulimic patient in which fluoxetine reversed both eating binges and vomiting but then resulted in restricted food intake, altered body image, and amenorrhea.

Ms. A, a 22-year-old woman, was 168 cm tall and weighed 56 kg. She had no previous psychiatric history. Two years prior to presenting for treatment she gradually began to experience episodes of increased appetite, with markedly increased food intake. She began to be concerned about her weight gain and would induce vomiting following each binge. The episodes increased in frequency and were associated with increasing anxiety that was relieved only by eating binges. She became irritable, impulsive, and increasingly depressed. Her social and familial relationships seriously deteriorated. Physical and laboratory examinations revealed no significant abnormalities, and there was no history of menstrual irregularity.

After the diagnosis of bulimia was established, Ms. A received fluoxetine, 20 mg/day, and weekly supportive psychotherapy. During the first month the dose was increased

gradually because of continued symptoms. One week after a 60 mg/day dose was reached, the frequency of eating binges and vomiting began to decrease. After 3 weeks, bulimic symptoms had almost completely disappeared and the patient was euthymic. One month after treatment at this dosage the patient developed amenorrhea and a preoccupation with weight gain; she began to restrict severely her caloric intake. Fluoxetine had to be discontinued when the patient's weight fell below 50 kg. One month later, bulimic symptoms recurred, the patient's weight increased, and the amenorrhea, as well as other anorexic signs, gradually disappeared.

It has been proposed that the abnormal eating patterns that characterize bulimia nervosa could result from an imbalance between facilitatory α -noradrenergic and inhibitory serotonergic pathways (2). Thus, drugs that potentiate 5-hydroxytryptamine (5-HT) activity may reduce bulimic symptoms. Some authors have proposed that these drugs might induce anorexia through a stimulation of 5-HT_{1D} receptors (3), which could enhance satiety (4). Although the neurobiology of anorexia nervosa still remains poorly understood, a serotonergic hyperactivity has been suggested to play a role. This could explain the appetite stimulant effect of 5-HT antagonists such as cyproheptadine (5). This hypothesis would place bulimia nervosa and anorexia nervosa on opposite poles of a clinical and pathophysiologic continuum.

To our knowledge, there are no reports of a fluoxetine-induced anorexia nervosa-like syndrome in a bulimic patient. The case reported here illustrates the potential importance of the serotonergic system in eating disorders and supports the possibility of inverse pathophysiologic pathways between bulimia and anorexia nervosa. This case may also highlight the possible adverse effect of 5-HT reuptake inhibitors when used in bulimic patients.

Lyell Syndrome and Lethal Catatonia: A Case for ECT

SIR: We would like to present the following case report.

Ms. A, a 43-year-old woman with a history of bipolar affective psychosis, had been prescribed carbamazepine, 200 mg/day, sulpiride, 600 mg/day, and perazine, 100 mg/day, for pending exacerbation of her psychiatric illness. Fourteen days later she developed a progressive exfoliative

skin disorder with multiple painless blisters of the face, trunk, arms, and mucosal surfaces of the mouth, eyes, and vulva. The patient was admitted to the local dermatology clinic and given a diagnosis of Lyell syndrome (toxic epidermal necrolysis), a rare severe toxic reaction to different drugs, including carbamazepine, characterized by epidermal blistering and peeling of the skin in large sheets (1). All psychotropic medication was withdrawn. High doses of steroid therapy (initial dose, methylprednisolone, 250 mg/day) and supportive care were administered. After a few days Ms. A exhibited mixed bipolar disorder with mood-congruent psychotic features (*DSM-III-R*) that progressed rapidly to full-blown lethal catatonia (2), a rare life-threatening disorder of psychomotor disturbances and autonomic dysregulation. The patient was given six unilateral ECT treatments within 2 weeks and showed a remission of lethal catatonia within hours and a remission of the affective syndrome within 2 weeks. Steroids were tapered quickly and the skin lesions disappeared within 4 weeks.

ECT is an effective and safe treatment for lethal catatonia (2), even in high-risk patients. Carbamazepine was the drug most likely responsible for Lyell syndrome in our patient, but we were nevertheless reluctant to administer other neuroleptic drugs, which are also less effective in lethal catatonia than ECT. Steroid therapy may cause affective and paranoid psychoses (3), but steroid-related catatonia is apparently very rare (4). Corticosteroids were advocated as a treatment modality for lethal catatonia in the preneuroleptic era (*DSM-III-R*). Continuous steroid therapy in our patient may have blunted the syndrome of lethal catatonia initially and may have contributed to its rapid remission during ECT.

Use of Pimozide in the Pisa Syndrome

SIR: The Pisa syndrome, a dystonic reaction that appears as a side effect of antipsychotic agents (1), is considered to be a subtype of tardive dystonia (2). It is usually difficult to treat this condition without discontinuation of antipsychotics (3). However, we report a case where the patient dramatically recovered from the Pisa syndrome following a change in medication from haloperidol to pimozide, a selective dopamine D₂ receptor agent, without any reduction in the clinical antipsychotic effects.

Mr. A, a 22-year-old man with mental retardation (IQ=44, Suzuki-Binet Test), was admitted to a psychiatric hospital with a diagnosis of schizophrenia. The patient initially received haloperidol, 9 mg/day; propicazine, 75 mg/day; and

biperiden, 3 mg/day. The dose of haloperidol was gradually increased to 27 mg/day and propericiazine to 225 mg/day over the next 4 weeks. Within the following week, Mr. A's trunk gradually developed a peculiar position, with side flexion of the body and backward axial rotation. The patient was considered to be suffering from the Pisa syndrome, since he fulfilled the criteria for tardive dystonia developed by Burke et al. (2) and showed the typical posture of this syndrome (1) without any other dystonic reactions.

The propericiazine was first discontinued, and then haloperidol was decreased to 18 mg/day over 4 weeks, but without any noticeable improvement. We then tried agents reported to improve tardive dystonia, such as promethazine, amantadine, tiapride, carbamazepine, and dantrolene sodium. Each of these was prescribed for more than 2 weeks with no benefit. Finally, we changed the patient's antipsychotic from haloperidol, 18 mg/day, to pimozide, 18 mg/day. From that time on, the dystonic symptoms gradually improved and almost completely disappeared within 1 week. The symptoms did not recur over the next several months.

We changed the antipsychotic agent for the following reason. There has been no report of selective D₂ antagonists causing the Pisa syndrome. The affinity of pimozide for D₂ receptors is higher than that of haloperidol in *in vitro* radioreceptor assay (4). This suggested that the activity of haloperidol at non-D₂ receptor sites may be responsible for the syndrome. For example, blockade of the sigma receptor, which haloperidol exhibits with a high affinity, is considered to play a role in dystonia (5).

Rare Presentation of Tardive Dyskinesia

SIR: Severe presentations of tardive dyskinesia (1) are frequently disabling because of difficulties in masticatory movements, severe tardive akathisia, or limb and finger movements. Respiratory or swallowing dyskinesias producing irregular respiratory rates or grunting noises have been

rarely reported (2). Therapeutic strategies, often irrelevant in treatment, are more difficult and ineffective in these cases (1). We observed a case of rare and severe presentation of tardive dyskinesia in a 57-year-old woman with a diagnosis of dysthymic disorder and histrionic personality disorder according to *DSM-III-R*.

Ms. A had been treated for several years with high potency neuroleptics, probably to contain agitation and anxiety unresponsive to benzodiazepines. Persistent tardive dyskinesia was diagnosed according to Schooler and Kane criteria (3) using the Rockland Simpson scale for tardive dyskinesia (4). Ms. A's total score was 48.

Upon admission Ms. A showed chewing movements, choreoathetoid movements of the tongue, blepharospasm, finger movements, akathisia, and lordosis with abnormalities of gait. These signs were associated with a continuous, rhythmic, clearly involuntary vocal emission, like a cry, the origin of which seemed to be laryngeal, defined by the patient as "illness of the cry."

The vocal emission (together with other signs) followed typical tardive dyskinesia patterns, disappearing only during sleep and worsening with anxiety, and its continuous occurrence affected severely the patient's speech and ability to fall asleep. Awareness of this symptom was higher than for the other symptoms, maybe because of the auditory feedback. During 2 years of illness, severity was reported to decrease if neuroleptic doses were increased and to worsen upon decrease or withdrawal. The severity also increased if anticholinergics were used. In the last 6 months severity was stable with Ms. A taking clothiapine, 40 mg/day. Withdrawal from medication induced a significant worsening of vocal emission and other symptoms.

Neurological examination and nuclear magnetic resonance imaging excluded an olivopontocerebellar syndrome, which was considered in differential diagnosis, as well as other neurological conditions possibly related to the vocal emission and other involuntary movements.

After 1 week of treatment with clonazepam, 8 mg/day, most symptoms decreased, except lordosis, gait disturbances, and the vocal emission (total Simpson scale score=38), which remained unchanged throughout the following 1-month observation period.

The similarity of our patient's symptoms with Tourette's disorder is worth noting. Our observations seem to be quite similar to cases of tardive Tourette's disorder reported in the literature (5).

Schizophrenia and Chromosomal Fragile Sites

SIR: Family, twin, and adoption studies have provided evidence that genetic factors play an important role in the etiology of schizophrenia, although no specific genetic mechanism has yet been identified. In recent years further information about the nature of the genetic effect has resulted from cytogenetic and molecular investigations. After the initial report of the cosegregation of schizophrenia with a partial trisomy of chromosome 5, linkage studies with genetic markers suggested the involvement of a susceptibility locus for this disease on the long arm of chromosome 5 (1). However, further studies did not confirm such results (2). In one survey, no chromosomal defects were found in a male schizophrenic population (3), although evidence of chromosomal fragile sites has been reported in schizophrenic patients with cutis verticis gyrata (4).

A cytogenetic investigation was carried out at a psychiatric hospital in 48 unrelated male patients, aged 28–58 years (mean=44.6 years), with chronic schizophrenia, diagnosed according to the *DSM-III-R* criteria and divided into five clinical subtypes (i.e., disorganized, paranoid, catatonic, undifferentiated, and residual). The control group consisted of 20 healthy male volunteers, aged 24–52 years (mean=37.5 years), recruited from nursing staff and physicians at the hospital. Cytogenetic analysis in blood lymphocytes, cultured by the method of Neri et al. (5) for identification of folate-sensitive fragile sites, showed a significantly higher presence of rare fragile sites in metaphases of schizophrenic patients than in the control group ($p<0.001$). The chromosomes most involved were 9 and 10, often with fragility at p21 and at q21, respectively. The fragile 9(p21) and fragile 10(q21) sites were present in 56% and 52% of patients, respectively, with a proportion of positive cells ranging from 2% to 17%, while fragility of chromosome 9 and 10 was found only in 15% and 25% of normal subjects, respectively, with a variability of expression from 1% to 6%. A lower frequency of fragile sites was observed on other chromosomes (i.e., on chromosomes 3, 8, 12, and 16). With regard to the X chromosome, the fragile site at Xq27 was detected in few cells, with no differences between patients and healthy volunteers. There was no difference in the presence of chromosomal fragility among patients of different schizophrenia subtypes.

Autosomal fragile sites have been regarded as normal variants associated with no specific clinical condition. The finding of a high frequency of fragile sites on chromosomes 9 and 10 in male schizophrenic patients indicates that fragility could have a role in the etiopathogenesis of schizophrenic disorder. Admittedly, since the fragile X site is difficult to detect in female carriers by chromosome analysis, our investigation was conducted only in male subjects and, therefore, these results need to be confirmed also in female patients. The identification of such chromosomal abnormalities associated with schizophrenia might provide important leads in the search for the chromosomal location of major genes in this disease.

Serotonin Syndrome

SIR: Harvey Sternbach, M.D. (1), did an excellent job of summarizing the rather disparate literature on clinical and preclinical aspects of the serotonin syndrome. We would like to add to his review our own experience with this phenomenon, which we believe to be unique in that our observations were made under the controlled conditions of the laboratory.

As part of our ongoing research on serotonergic function in humans, we have been investigating the neuroendocrine and behavioral effects of intravenous L-tryptophan (L-Trp) in a number of neuropsychiatric disorders and during treatment with a number of neuropharmacological agents (2). In one of our studies (3), we administered doses of L-Trp ranging from 4.5 to 7.0 g i.v. to nine patients with major depression who were receiving treatment with the monoamine oxidase inhibitor (MAOI) tranylcypromine. In addition to observing an enhancement of the prolactin response to L-Trp during tranylcypromine treatment, presumably reflecting enhanced serotonergic function, four of our nine patients developed a distinctive neuromotor syndrome following L-Trp infusion during tranylcypromine, but not during placebo, treatment. Symptoms included hyperreflexia, ankle clonus, nystagmus, incoordination, tremor, myoclonic jerks, and nausea. There were no obvious cognitive changes or seizures. One patient with a previous history of hypomania developed elated mood and pressured speech. The full syndrome generally lasted 6–12 hours, although isolated symptoms persisted for up to 24 hours in individual patients, with complete resolution thereafter. There were no evident sequelae. There were no differences in peak prolactin, mood, or autonomic responses between patients with and without the syndrome, but those with the syndrome had received tranylcypromine for a shorter period of time (mean=8.3 days, SD=4) than those without the syndrome (mean=22.6 days, SD=5.4).

Interestingly, in similar studies using the L-Trp infusion to assess the serotonergic effects of the selective and potent serotonin reuptake inhibitor fluvoxamine (4), we saw little of the full-blown syndrome described above, although a few patients developed some isolated myoclonic jerking.

Our findings suggest that the ability of a drug to induce the serotonin syndrome in humans depends not only on its ability to enhance potentially serotonergic function but also on the mechanism by which it effects that enhancement. MAOIs may have

a particular propensity for inducing the syndrome, especially early in treatment, before compensatory mechanisms have come into play. With the increasing availability and utilization of drugs with potent effects on serotonergic systems, we agree with Dr. Sternbach that increased vigilance for these adverse effects is critical.

The (Ab)use of Computers

SIR: Computers facilitate the collection, organization, and manipulation of data from large numbers of patients and have great value for clinical, research, and administrative tasks (1, 2). However, computers can be abused and mislead us. Several obvious errors in our computerized data base led to a process of reviewing data prior to computer entry which, in turn, identified other less obvious, but serious, pitfalls of computerizing unreviewed data.

After a 1-hour orientation to the use of an optically scannable patient consultation record (1), residents and fellows used it to record data on all patients seen by our medical center consultation/liaison service. At the end of each consultation, the patient consultation record and a copy of the initial consultation note were reviewed by a senior attending physician before the patient consultation record was scanned for data entry. Incomplete or inaccurate patient consultation records were returned by the reviewer to the trainees for correction and re-review. After noting a high number of inaccurate forms returned, we systematically collected data on rates and types of patient consultation record errors for a 10-month period. There was a token incentive (a free monthly lunch) for the trainee with the highest rate of initially accurately completed patient consultation records.

The monthly rate of accurate completion ranged from 0% by a resident in his first month of rotation to 86% by a fellow in his sixth month. Overall, during the period of the review, 50% of the patient consultation records initially had at least one error, with half of the rejects having more than one error. When rejected patient consultation records were reviewed for type of error, 50% had missing data, 33% factual errors, and 58% errors of interpretation.

In addition to providing more accurate data, close review of the forms prior to computer entry offers an opportunity to evaluate and improve trainee performance. A trainee's accuracy of patient consultation record completion seemed to par-

allel his or her clinical performance on the consultation-liaison rotation, i.e., inaccurate completers were poor performers and vice versa. Record accuracy problems often alerted us to trainee needs for specific teaching interventions. Finally, the elimination of incomplete forms by review enabled us to identify a mechanical problem with the optical scanner. When the computer printout indicated a large number of forms with no data for a particular item, our knowledge that such incomplete forms were not entered led to a speedy correction of the hardware problem.

We remain enthusiastic about the many uses of computers in a psychiatric setting, but our experience confirms the well-known motto of the computer industry, "Garbage In, Garbage Out." In addition to computer checks for completeness, we strongly recommend professional reliability review of all clinical data prior to computerization.

Alcohol and Addictions

SIR: I enjoyed reading the overview of substance abuse disorders written by the Group for the Advancement of Psychiatry (GAP) Committee on Alcoholism and the Addictions (1). I would, though, like to make two points.

When the authors discussed the treatment of substance abusers, the goal of abstinence was strongly suggested. While the feasibility of controlled drinking was discussed, and it was mentioned that certain patients can achieve a stable recovery with controlled drinking, controlled drinking was essentially portrayed as doomed to fail. Consequently, at the outset of treatment, it was suggested that the goal of abstinence should be conveyed to all patients. There are, however, considerable data that support controlled drinking as a viable treatment goal (2). In addition, whether or not moderation of drinking will be successful, it can frequently be critical at the outset of treatment to develop a controlled drinking contract with patients who want to try this approach so that they can discover for themselves whether controlled drinking is possible for them. If moderating drinking proves unsuccessful, then abstinence should be considered. In my experience, denial, if it is operating, can frequently be broached by this method rather than by insisting on abstinence at the start of treatment.

The second point concerns self-help organizations. The authors discuss Alcoholics Anonymous (AA), which is an important, if not sometimes essential, treatment modality. They also mentioned Narcotics, Gamblers, Pills, Cocaine, Drugs, and Overeaters Anonymous. There are, however, two other self-help organizations designed to be of help to the substance abuser that were not mentioned: Rational Recovery and Secular Organizations for Sobriety. For patients who cannot connect with AA or other similar programs, these organizations should be suggested. Their philosophies are strikingly different than that of AA or any of the other self-help programs based upon the philosophy of AA. Such organizations may fit

better with the character structure of some patients who find AA distasteful. There may be times when resistance to AA may not need to be "worked through"; instead, the resistance could be accepted.

MICHAEL LEVY, PH.D.
Andover, Mass.

SIR: The recent article by the GAP Committee on Alcoholism and the Addictions "reviews the role of the psychiatrist in the evaluation and treatment of patients with substance use disorders." The review covers the major areas in assessment and treatment thought pertinent to psychiatrists. Although such a review article clearly cannot cover all the issues, we would like to note two important areas overlooked by this report.

The first is the absence of references to behavioral formulations of alcohol and drug abuse and the efficacy of behavioral therapies for these disorders. This is surprising given the utility of behavioral theories. For example, the concept that drugs can serve as reinforcers similar to food and water has been used to understand how drugs that produce little withdrawal can be drugs of dependence. This formulation has also led to effective procedures for screening new compounds for abuse liability and for examining genetic and environment factors thought to control drug use. Behavioral approaches have also produced some of the more impressive abstinence rates (1). In addition, behavioral approaches (e.g., relapse prevention) have slowly been incorporated into many different treatment approaches.

The second area overlooked is that, although alcohol, cocaine, marijuana, opioids, and other drugs are mentioned, nicotine is ignored. This stance is consistent with the absence of any mention of nicotine dependence or smoking in the recent National Consensus Standards for Postgraduate Medical Fellowship Training in Alcoholism and Drug Abuse put forward by the American Academy of Psychiatrists in Alcoholism and the Addictions (2). These absences suggest nicotine dependence is not a disorder of sufficient importance to be addressed by psychiatrists. In reality, smoking causes three times the number of deaths as all other forms of drug abuse combined, can be as intractable as other severe dependencies, and is linked to several psychiatric disorders (3).

Part of the reason behavioral approaches to drug abuse and smoking as a form of drug abuse were omitted from the GAP report may be that these are very seldom addressed in traditional alcohol/drug abuse programs (4). Even so, reports such as the GAP report should highlight issues that have been scientifically shown to be of importance but have been ignored by the current research and treatment establishments.

JOHN R. HUGHES, M.D.
WARREN K. BICKEL, PH.D.
STEPHEN T. HIGGINS, PH.D.
Burlington, Vt.

SIR: The GAP Committee on Alcoholism and the Addictions presented an excellent overview for the general psychiatric practitioner on the substance abuse disorders. Perhaps one of the reasons for the persistent resistance of our colleagues to accept the patient with substance abuse as "one of our own" is the semantic separation we foster between the substance abuse disorders and other psychiatric disorders. The Committee notes, for example, the "high prevalence of psychiatric disorders among patients with substance abuse problems." The psychiatric disorder most common in patients with "substance abuse problems" is, in fact, a substance abuse disorder. As the medical director of a substance abuse program, I strive to teach medical students rotating through our program that they need not bemoan the absence of "real" psychiatric patients on our unit. Rather, substance abuse will likely be the most common psychiatric disorder they will come in contact with in their future medical practice. When the psychiatric community can begin to accept the substance abuse disorders as a disorder equal in weight to all other psychiatric disorders, we will have made a critical step in acknowledging our primary role in the recognition, assessment, and treatment of this patient population.

BRYON ADINOFF, M.D.
Charleston, S.C.

Dr. Khantzian Replies

SIR: Our GAP report on substance abuse disorders as a psychiatric priority struck the theme that the problem of substance abuse has been neglected or responded to insufficiently by the medical profession in general and by the psychiatric profession in particular. It is a problem that keeps eluding us, and we keep denying how basic and pervasive the problem is. At the same time, we generalize about treatments and, intentionally or inadvertently, fail to consider the subtleties of individual patient needs or the advantages of treatment approaches that are less familiar to us or compatible with our pet ideologies or theories. The three letters authored respectively by Dr. Levy, Dr. Hughes and colleagues, and Dr. Adinoff correctly and legitimately underscore that the GAP Committee on Alcoholism and the Addictions, despite our best intentions, did not cover all the bases. These letters bring to our attention basic and added important dimensions of alcoholism and addiction that should be considered.

Dr. Levy's letter raises the controversial issue of whether alcoholics can ever resume controlled drinking. There is a plethora of rigid opinions about this in the field that, in their extremes, either place patients at risk, creating unrealistic or

unachievable goals, or cause other patients to abandon treatment when an unswerving attitude about the requirement for abstinence is prematurely and insistently advocated. I personally agree with Dr. Levy and have described in the literature (1) how we can establish an alliance with our patients, usually less severe cases, in collaborating with them and testing whether controlled drinking is a possible or realistic option. I also agree with Dr. Levy that alternatives to 12-step programs such as AA are necessary. I suggest that, for some, the most important ingredient in recovery is the association and interaction with others who are recovering, which groups like Rational Recovery and Secular Organizations for Sobriety provide. Such opportunities for interaction are antidotes to the pervasive, crippling isolation and self-absorption that so powerfully perpetuates substance abuse disorders.

The letter by Dr. Hughes and colleagues rightfully points out omissions in two important areas, namely 1) overlooking behavioral formulations of substance abuse disorders and the efficacy of behavioral therapies, and 2) the failure to mention nicotine as an addictive drug. Dr. Hughes and associates are probably right that this in part reflects that behavioral approaches and nicotine addiction are seldom addressed in most substance abuse programs. Consistent with their speculation, I also know that few, if any, of us on the committee have directly worked in these areas, although most of us in retrospect would agree that both areas should have been addressed. Finally, I am also in agreement with Dr. Adinoff that the most common psychiatric disorder in patients with substance abuse problems is substance abuse disorder. A fact that keeps escaping clinicians and others is that substance abuse, as much as it is anything else, is a psychiatric condition.

Notwithstanding these omissions, I believe it was an accomplishment to bring our GAP report to fruition in the *Journal* and to reach the consensus we did as a committee. Prior to 1986 there was no GAP Committee on Alcoholism and the Addictions. At its inception we believed we could produce a position paper within a year. It took 4 years, but I am pleased and satisfied we were clear enough about what we did include and cover. We appreciate being astutely reminded by thoughtful colleagues about what else we might have covered or stated more clearly.

Kleptomania and Shoplifting

SIR: Marcus J. Goldman, M.D. (1), cited our article (2) as the source for his statement that "kleptomania may account for a substantial proportion of the staggering 40 billion dollars in business losses attributed to shoplifting each year."

I wish to make two points regarding this citation. First, our article stated that "shoplifting losses in the United States have reached an annual amount of approximately 24 billion dollars" and not 40 billion. Second, we never indicated that kleptomania accounted for a "substantial proportion" of shoplifting losses. On the contrary, we stated that "[kleptomania] is, in our experience, infrequently observed" in apparently nonsensical shoplifting cases. Indeed to the current date Dr. Atcheson and I have estimated that less than 10 of the hun-

dreds of shoplifters we assessed would be considered to be suffering from this disorder.

The major findings of our initial clinical research regarding the underlying causative factors in those apparently nonsensical cases of shoplifting that we assessed, clearly indicated that they were most definitely *not* of the kleptomania type, differing on virtually all the DSM criteria for kleptomania quoted by Dr. Goldman.

Furthermore, our cited article, in fact, indicated in the vast majority of the cases that we assessed from 1979 to 1982 (and, incidentally, our later clinical assessments have strongly supported these earlier findings), that at psychodynamic levels these offenders' actions were not at all "nonsensical." In our article we categorized the following (nonmutually exclusive) psychodynamic motivations of (apparently) nonsensical shoplifting 1) as a reaction to stress, 2) as a regressive, symbolic act, 3) as unconscious retribution, 4) as unconscious manipulation, 5) as conscious manipulation, and 6) as a response to actual or anticipated personally meaningful loss.

Our experience also suggests that the alternate diagnoses of conduct disorder or antisocial personality disorder do not often fit the persons who have committed "nonsensical" acts of shoplifting. These sorts of shoplifters, and others who committed various kinds of theft and whose actions appear (only) at a superficial level to be "nonsensical" (but which are not), we termed "atypical theft offenders." We introduced this term elsewhere (3).

The atypical theft offender conceptualization is increasingly appropriately employed by both clinicians and lawyers in Canada and elsewhere. It is hoped that, with further refinement of this conceptualization, at some point this syndrome will be incorporated into a future edition of DSM.

The atypical theft offender syndrome is outlined in greater detail in a book that I am presently completing. Included in this latest project are detailed means of obtaining clinically relevant and judicially useful assessments as well as ways of providing specialized treatment in such cases.

WILL CUPCHIK, PH.D., C.PSYCH.
Toronto, Ont., Canada

Dr. Goldman Replies

SIR: I would like to thank Dr. Cupchik for pointing out several important editing errors in my article on kleptomania. Indeed, the article by Dr. Cupchik and Dr. Atcheson states that shoplifting losses have been estimated at 24 billion dollars per year and not 40 billion as I stated. Additionally, in my article, I stated, "Kleptomania may account for a substantial proportion of the staggering 40 billion dollars in business losses each year (1)." While I attributed this to Drs. Cupchik and Atcheson, it is misleading since I meant only to use the statistic. Indeed, my sentence should have read, "Since shoplifting losses have been estimated at 24 billion dollars (1) it is possible that kleptomania may account for some of this loss."

Editing errors aside, I attempted to incorporate cases that approximated *DSM-III-R* criteria but often found that the data were insufficient to accomplish this. In discussing Dr. Cupchik and Atcheson's loss-substitution-by-shoplifting hypothesis in my article and given little data from which to draw diagnostic conclusions, I suggested that some of his patients may have suffered from kleptomania, a notion strongly disputed by Dr. Cupchik based on his interpretation of the *DSM-III-R* criteria.

In actuality, many of the vignettes presented by Drs. Cupchik and Atcheson in their article contained characteristics not inconsistent with the findings of my review of the literature. Indeed, their article revealed examples of those who, for example, had sexual disturbances, anxiety and depression, risk taking, a sense of excitement, remorse and embarrassment, or uncontrollable drives.

Furthermore, in using *DSM-III-R* to rule out kleptomania in his letter, Dr. Cupchik states that his patients used theft, for example, as a means of exercising either conscious or unconscious retribution or manipulation and thus the thefts are not "nonsensical"—of this I have no doubt. Indeed, the majority of early psychoanalytic writers felt that kleptomania was motivated by unconscious revenge or anger against, for example, ambivalently held objects. While *DSM* states that the theft cannot be the result of anger or vengeance, this is taken to mean conscious anger or vengeance. *DSM* does not discuss unconscious motivations when describing impulse disorders, nor should it, as it would make unconscious anger fair game. Dr. Cupchik may be confusing diagnostic criteria with etiology. Indeed, the fact that the acts are not nonsensical from a psychodynamic point of view, as Dr. Cupchik stated, is true but irrelevant as it pertains to diagnostic or inclusion criteria. I am also concerned about Dr. Cupchik's reductionistic model for theft and his suggestion that a new category be created for possible inclusion in *DSM*. Putting people into a myriad of different diagnostic categories based on their varying unconscious motivations seems fine for psychodynamic texts, but not for *DSM*, since the point of this manual is diagnostic and not etiologic. At best, I would perhaps argue for a less restrictive set of diagnostic criteria for kleptomania, rather than creating new disorders.

As for Dr. Cupchik's thesis that the "moral majority" represents a subgroup distinct from those with kleptomania or other stealing behaviors, I suggest that those who do not meet the criteria of the "moral majority" end up in prison, rather than in a psychiatric institute where they can be studied, because they are deemed less interesting or less likely to be rehabilitated by the courts and ostensibly more guilty because of their diminished financial or social status. I suggest that the drive to steal—once, occasionally, on a sustained level, "nonsensically," or otherwise—can be found in members of all socioeconomic groups. The one-time or infrequent offender, however, may give us clues and insights into the more severely ill.

MARCUS J. GOLDMAN, M.D.
Boston, Mass.

Clozapine Concentrations and Clinical Response in Schizophrenic Patients

SIR: Paul J. Perry, Ph.D., and his colleagues (1) have reported a study of 29 inpatients suffering from refractory schizophrenia who received approximately 400 mg/day of clozapine for 4 weeks. The investigators claimed to have identified a mini-

mum therapeutic plasma clozapine concentration of 350 ng/ml. The basis of their conclusion was on a categorization of the patients into "responders" and "nonresponders" and subsequent analysis of true and false categorizations with receiver operator characteristic curves.

The use of receiver operator characteristic curves to depict concentration-response relationships may be justified when the response variable is clearly categorical and binary but presents difficulties when there is a continuous variation in the degree of response which must be arbitrarily dichotomized in order to be accommodated in the receiver operator characteristic model. The accepted method in this area is to employ a correlational analysis of concentration and response, both to be considered as continuous variables. Fortunately, the authors have provided complete data from this study, enabling us to perform such an analysis.

Dr. Perry and colleagues used a definition of response which was derived from a clozapine study by Kane et al. (2): namely that "improvement or response was defined as a 20% or greater change in the total Brief Psychiatric Rating Scale (BPRS) score from baseline to the end of week 4 of fixed dosing and a final BPRS score of 34 or less." We constructed alternative receiver operator characteristic curves, using slightly different definitions of response (20% and 30% improvement over baseline without any minimum score) and found no plasma level that discriminated reliably between "responders" and "nonresponders," suggesting that their finding was a product of the particular definition of response that they employed.

Correlational analysis revealed no significant correlation (r between -0.16 and -0.32) between degree of clinical improvement, defined as either absolute or proportional improvement over baseline, and any measure of plasma drug concentration (clozapine, norclozapine or total, expressed in absolute or logarithmic terms). A further analysis by sex revealed some unexpected findings. Even though the mean values for men and women did not differ on any clinical or drug-related variable, the correlation between response and total clozapine plasma levels was significantly negative for men ($r = -0.51$ for BPRS score improvement, $p < 0.05$; $r = -0.45$ for percent improvement, $p < 0.05$) but positive, although not significantly so, for women ($r = 0.50$ and $r = 0.52$, respectively). Similar results were obtained when clinical improvement was correlated with clozapine or norclozapine levels or the log-transformed values. Furthermore, correlations for clozapine and clozapine plus norclozapine were reliably different for men and women ($p < 0.05$; two-tailed test).

It is unclear whether the plasma levels were obtained at consistent time intervals after the clozapine dose was administered. It is possible that the lack of correlation between therapeutic response and plasma levels and the puzzling results obtained by examining men and women separately may have been a result of variations in the blood sampling time from the last dose.

We remain unconvinced that the reported data support the notion of a therapeutic threshold for clozapine, but we suspect one may be established when lower levels are considered.

Dr. Arndt Replies

SIR: We appreciate the interest Dr. Owen and his colleagues show in our article dealing with response to clozapine. They point out what appears to be a lack of correlation between clinical improvement and plasma drug concentration. As we discussed in response to a previously published letter (1), we did perform a correlational analysis and the results were significant. To recapitulate: a significant multiple correlation of BPRS at week 4 was found with mean weekly clozapine controlling for baseline BPRS. One patient described elsewhere (2) with neuroleptic malignant syndrome was excluded from the analysis.

On the subject of using receiver operator characteristic curves and using correlations, we feel that each approach has its place. An early version of our article did include both types of analysis. In the interest of space and relevance, however, this portion of our results was deleted from the published version. Correlation coefficients determine if, and to what extent, variables are related in a linear fashion and how well the regression equations predict points on one scale. However, correlations offer little direct information regarding decisions about specific patients. For instance, a linear scale only suggests more or less of something and not a presence or absence, response or nonresponse. We dichotomized our linear scale for two reasons. As decisions need to be made about the success of a treatment, we felt that it was more clinically meaningful to analyze response versus nonresponse rather than to assess our ability to predict points on an arbitrary rating scale, the BPRS. We also used the specific dichotomizing criteria to allow for comparison with previous research in this area (3).

Identification of Mood Variance in Depression

SIR: Donald P. Hall, Jr., M.D., and colleagues (1) suggested that the self-rated mood of depressed subjects during daytime hours shows greater variability and has ultradian rhythms of greater amplitude than that of normal subjects. Although the authors carefully identified several limitations of their study, two specific aspects of the study warrant further comment.

First, the authors identified an "ultradian rhythm" for each subject using only 12 hourly self-ratings. The crossover

method used by the authors will identify a cycle in almost any data. Whether this cycle has any intrinsic meaning as a characteristic of the individual—or indeed any ultradian rhythmicity—requires repeated measures to determine whether the values calculated for the length and amplitude of the cycle are consistent across days. The complex demodulation analysis illustrated in figure 3 results in "highly accurate" curve fitting because it permits the amplitude of the fitted cycle to vary markedly across time. Therefore, interpreting the analysis as supporting the existence of an ultradian rhythm with a specific amplitude seems to go well beyond the available data.

Second, several characteristics of the depressed patient group raise questions about the meaning and generalizability of the observed higher mood variability. The depressed group was diagnostically heterogeneous (as was the comparison group of staff members and paraphilic patients). The depressed patients were not very depressed—the mean Hamilton Rating Scale for Depression score was only 16 and the mean Visual Analogue Mood Scale score was 41. The medication status of the patients was not specified, and the observed mood variability may in part have reflected a response to antidepressant medications. Finally, axis II diagnoses were not reported.

The mood pattern in the depressed group—mild to moderate depression with higher mood variability than the comparison group—is similar to that which we documented in "depressed" patients with borderline personality disorder using twice daily Visual Analogue Mood Scale ratings over 2 weeks and was quite different from the pattern we observed in medication-free patients with major depressive disorder—moderate to severe depression with little variability (2). The authors' claim that depressed patients in general have greater mood variance than nondepressed individuals should be treated with some skepticism. The varieties of depressive experience are many, and the mechanisms of mood regulation underlying them are likely to be correspondingly varied.

As the authors suggested, deceptively simple tools like the Visual Analogue Mood Scale may well contribute to our understanding of the mechanisms of mood regulation and to better differentiation among patients with "depression," particularly as these tools are applied in larger populations with carefully delineated clinical characteristics, including the presence or absence of comorbid axis II disorders.

REX WILLIAM COWDRY, M.D.
Washington, D.C.

Dr. Hall and Associates Reply

SIR: Dr. Cowdry's comments are noted and reflect a thorough review of our study; however, we question the use of his data to criticize our findings. Limitations in the design of his own study may explain the discrepancy in our reports. His methods are based on the assumption that mood varies in a random pattern. Our study, however, suggested that mood variance is not random but follows a cyclical pattern. By using

only two mood assessments (morning and evening) over the course of the day he fails to detect cycles less than 24 hours in length. Our study utilized 13 hourly mood assessments over the course of the day and represents a more valid method of assessing intradaily mood variance.

Further, our finding of increased mood variance in depressed persons is conceptually consistent with research supporting a dysregulation hypothesis of depression. This theory holds that affective disorders may involve a failure in the regulation of neurotransmitter systems rather than simply increasing or decreasing the baseline activity (1). Perturbation of homeostatic mechanisms with the establishment of a new baseline of mood appears to be accompanied by increased variability around that baseline.

Our article represents the first report describing a detailed methodology to approach the study of ultradian cycles of mood. One other study has described ultradian cycles of mood (in normal subjects), but methodology was only briefly described (2). As an exploratory study, our methods and focus will require modification as research continues. Although we disagree with Dr. Cowdry's implication that complex demodulation can be used to demonstrate cycles with a high degree of accuracy ($r^2=0.95$) in almost any data, we agree that the program does not provide the specificity to be used alone as a method to detect cycles. For this reason, we also relied on visual inspection of the raw data time series plots. We readily observed ultradian cycle periodicity in the raw data plots of the majority of subjects tested, as we sought to illustrate in figures 2 and 3 of our article. Complex demodulation is not a required element of this study and in future studies it may be necessary to replace it as a method to describe goodness of fit. Amplitude and period can be calculated without complex demodulation by simple measurements of raw data plots.

Regarding the sample populations utilized in our study, we designed the study to make an exploratory assessment of mood variance in depression. Follow-up studies are required to look at more homogeneous depressed groups and control groups. Dr. Cowdry's criticism of our use of heterogeneous groups appears inconsistent when he has cited the homogeneous groups in his own study as a possible bias because such groups may be atypical for the disease. In the absence of research wards designated for the study of nonmedicated patients, it was not feasible to perform this study on nonmedicated patients, and we hope that investigators with such capability will evaluate this question.

Twins and Eating Disorders

SIR: Kenneth S. Kendler, M.D., and his associates reported in their excellent article (1) that, in determining zygosity, they found 590 monozygotic twin pairs and 440 dizygotic twin pairs, with three pairs uncertain. Thus 590/1033 or 57.3%

were monozygotic. The usual proportion of monozygotic twins is 33%. This discrepancy suggests a sampling bias in this cohort study of female twins.

Dr. Kendler and colleagues indicated that one limitation of their study was that twins may not be representative of the general population with respect to eating disorders. Given their finding of a high proportion of monozygotic twins in their sample, the findings in this study may not be representative of twins in the general population either. Replication of these points in future studies is indicated to expand our understanding of the epidemiology of eating disorders.

JONATHAN G. SOLOMON, M.D.
Dover Air Force Base, Del.

Dr. Kendler Replies

SIR: I appreciate Dr. Solomon's interest in our recent article. Dr. Solomon is correct that in Caucasian populations of both same-sex and opposite-sex twin pairs approximately one-third of all twins are monozygotic (1). However, in samples of only same-sex pairs, such as those we studied, approximately 50% of the pairs are monozygotic. This is only an approximation, as the rate of twinning (particularly dizygotic twinning) varies across countries, even among Caucasian populations (1). It is likely that we have a slight excess of monozygotic twins in this study, but the excess is far smaller than Dr. Solomon would suggest. For example, in volunteer twin studies where subjects are recruited through advertisements in newspapers, newsletters, etc., approximately two-thirds of the population is monozygotic (2). Thus, our results are consistent with a slightly increased probability that monozygotic female same-sex pairs will cooperate compared to dizygotic pairs. However, this bias is probably a relatively modest one.

Regarding the Use and Accuracy of the Family History Method

SIR: The title of a recent article by Kenneth S. Kendler, M.D., and colleagues (1), implies that family history obtained from an affected twin reflects her personal psychiatric history rather than the true history of the parent on whom she is reporting. Unfortunately, the design of this study and the data reported do not support this conclusion.

For example, the authors concluded that family history is substantially influenced by the informant's psychiatric history, but that the size of the sample of twin pairs discordant for alcoholism was too small to provide a powerful test. This

is extremely misleading. The absence of an association for alcoholism is not due to insufficient power, but due to the strong agreement between the twins on their parents' diagnosis of alcoholism. From the authors' data, one can calculate kappas of 0.73 and 0.68 for twin agreement on the mother's and father's alcoholism history, respectively. What the authors have demonstrated for alcoholism is evidence that family history is a reliable study method.

The design of the study by Dr. Kendler and colleagues cannot yield information regarding the relative sensitivity or specificity of affected versus unaffected twins in reporting on their parents since we do not know the "true" diagnostic status of the parent. Table 1 showed that even unaffected twins reported ill parents without agreement from the other twin. Yet, the statistical method used by Dr. Kendler and colleagues tested for association between informant diagnosis and parent diagnosis. Thus, it incorrectly treated all cases reported by the affected twin (unconfirmed by the unaffected twin) as false positives and all cases reported by the unaffected twin (unconfirmed) as true cases.

In the absence of data on the parents' "true" diagnosis, we have no reason to believe that one or the other twin was more or less accurate in the history she provided. An affected twin may well have reported an affected parent more frequently, but there is no reason to believe that this constitutes an incorrect or biased report, as implied by the article's title.

An appropriate test of the accuracy of the family history method would compare agreement and disagreement between the twins' family history report and a "gold standard" such as direct interviews with the parents. Such a study would produce estimates of the diagnostic sensitivity and specificity of the family history method. In fact, Thompson et al. (2) used this method and have reported that family history yields high specificity and modest sensitivity for major depression and alcoholism, and low sensitivity for generalized anxiety disorder.

In order to prove that the affected status of the informant introduces systematic diagnostic bias to family history, one would have to show that affected informants overestimate illness (report false positives) and unaffected informants underestimate illness (report false negatives). The authors have not done this. To suggest that the family history method is flawed in the absence of such data is not justified.

Even the most thorough investigator will need to rely on family history information for some relatives because of death or refusal of direct interview. Assertions that such history is biased are premature.

EWALD HORWATH, M.D., M.SC.
New York, N.Y.

Dr. Kendler Replies

SIR: While I appreciate Dr. Horwath's interest in our recent article, I disagree with several of his conclusions. He is, however, completely correct in asserting that our design does not allow us to determine the "relative sensitivity or specificity of

affected versus unaffected twins in reporting on their parents." We wrote in the article: "Our results do not address the crucial question of whether individuals with a history of a psychiatric disorder are more or less accurate informants about psychiatric illness in their relatives than are individuals who report no personal psychiatric history." We have, in the last 2 years, personally interviewed most of the living parents of these twins and intend to directly address this issue shortly.

I also agree with Dr. Horwath that our sample size of twins discordant for alcoholism was too small to provide a powerful test of our hypothesis. This small number was due to several factors, especially the low base rates for alcoholism in this sample and the relatively high agreement between twins in their reporting on alcoholism in their parents.

I am unable to follow Dr. Horwath's logic, however, when he claims that we treated all cases reported by an affected twin as false positives and those reported by the unaffected twins as true cases. Our design was entirely agnostic with respect to which twin from discordant pairs was accurate in her family history diagnosis. We merely tested the hypothesis, which was confirmed for major depression and generalized anxiety disorder, that in discordant pairs, affected twins more often reported a family history diagnosis in their parents than did unaffected twins.

Dr. Horwath goes on to claim that we have no basis to conclude from our data that the family history is flawed. Again, I disagree. While he correctly points out that we cannot discriminate between false positive reports from affected individuals and false negative reports from unaffected individuals, our results do clearly suggest that at least one of these factors *must* be operating. Otherwise, we would have found no association between personal psychiatric diagnosis and family history reporting in our discordant pairs. Since either false positive reports from affected individuals or false negative reports from unaffected individuals constitute a bias in the family history method, our conclusions stand.

Richmond, Va.

Prevalence of Abnormal Movement Disorders Associated With Neuroleptics

SIR: Vikram Khot, M.D., and Richard Jed Wyatt, M.D. (1), deserve our thanks for their review of published data on the prevalence of tardive dyskinesia and of spontaneous dyskinesia in different age groups. When considering the alleged prevalence of the former, it is clearly essential to subtract the latter to arrive at a true prevalence figure for "real" tardive dyskinesia. However, I am unhappy about one aspect of their study. They accepted in their group of "spontaneous" dyskinesias any patient with a rating of 2 or higher for whom the authors "provided reasonable assurance that the patient did not have a history of neuroleptic exposure of more than 3 months." This was on the basis of the assumption that neuroleptic-associated dyskinesia does not begin in patients who have been treated with neuroleptics for less than 3 months. However, this argument is potentially circular. What we really need to know is the dyskinesia rate in patients who have *never* been treated with neuroleptics. This could then be compared with the rate in a) patients ever treated, b) patients treated for less than 3 months, and c) patients treated for more than 3 months. Are such data available from the studies examined by the authors? and if so, Could they not be presented?

A second, and equally important, question is the prevalence

of permanent tardive dyskinesia in patients withdrawn from neuroleptics. This involves a similar analysis that additionally takes account of the remission rate of tardive dyskinesia at varying time intervals after stopping neuroleptic treatment. Here, the equivalent question is: by how much does the prevalence, at a given number of years after stopping treatment, of neuroleptic-associated dyskinesia exceed that of spontaneous dyskinesia? If one undertook the same exercise, might the two prevalence rates be the same after, say, 5 years? Such an analysis would be of great clinical and medicolegal importance.

REFERENCE

1. Khot V, Wyatt RJ: Not all that moves is tardive dyskinesia. *Am J Psychiatry* 1991; 148:661-666

N.P. QUINN, M.D.
London, England

Dr. Wyatt and Dr. Khot Reply

SIR: Dr. Quinn raises an important issue when he asks about the prevalence of abnormal involuntary movements in patients never treated with neuroleptics versus those treated for less than 3 months. While there are probably too few well-controlled studies to reliably assess the incidence across multiple age groups, we believe there is sufficient evidence to conclude that it is rare for tardive dyskinesia to develop within 3 months of treatment. The evidence includes the following observations: 1) In most animal studies, tardive dyskinesia-like movements are not observed until at least 2-4 months after neuroleptics are initiated (1). 2) Only a few human studies report the occurrence of tardive dyskinesia within three months of introducing a neuroleptic, and some of these reports may include patients with initial dyskinesias (initial dyskinesia quickly and spontaneously remits and therefore is different than tardive dyskinesia). If tardive dyskinesia were more common during this period, one would expect to see a flood of case reports. 3) Prospective longitudinal studies of tardive dyskinesia development indicate about a 3% incidence in the first year of treatment for most age groups (2) (elderly patients may be at greater risk [3]). If this occurrence is evenly distributed throughout the first year, the incidence for the first 3 months would be less than 1%. 4) Of several hundreds of tardive dyskinesia patients we have seen, only one has developed tardive dyskinesia-like movements early in the course of neuroleptic administration. In this case, a 66-year-old woman developed mouth and tongue movements 3 months after beginning treatment for an acute psychotic episode related to a small stroke. For these reasons we believe it is unlikely that including patients with less than 3 months neuroleptic exposure in our never-treated group significantly distorted the prevalence of spontaneous dyskinesia.

Dr. Quinn also raises the interesting question of whether neuroleptic-induced abnormal movements dissipate when treatment is discontinued to the point that their incidence approaches that of spontaneous dyskinesia. While there are no published studies that clearly answer this question, this incidence can be estimated by making several assumptions. Casey (4), while following a group of 27 middle-aged tardive dyskinesia patients (although patients were on neuroleptics, it is not clear that some of them did not have spontaneous dyskinesias) for 5 years, attempted to gradually reduce the neuroleptic dose and ultimately to discontinue it. Discontinuation was possible in 10 patients. Of these 10, the Abnormal Involuntary Movement Scale score

for eight decreased by more than 50%; of the eight patients, those who showed abnormal movements at the end of 5 years were still improving. Assuming the 10 patients in the Casey study are representative of the 50- to 59-year-old tardive dyskinesia patient population (who can tolerate neuroleptic discontinuation), we would predict that 20% of tardive dyskinesia patients will have permanent abnormal involuntary movements (as defined by less than a 50% decrease after 5 years following neuroleptic discontinuation). In figure 2 of our report, we noted that about 15% of patients, ages 50-59, treated with neuroleptics for more than 3 months will develop "true" tardive dyskinesia. Thus, 3% (20% of 15%) of all 50- to 59-year-old patients exposed to neuroleptics would be expected to develop permanent tardive dyskinesia. Paradoxically, the risk of spontaneous dyskinesia for patients in this age group is 25%, or more than 8 times greater than the risk for permanent tardive dyskinesia.

The Casey study is substantially different than a study by DeVeaugh-Geiss (5), which reported little or no further improvement in tardive dyskinesia patients 1 year after neuroleptic discontinuation. It is, however, in agreement with a study by Klawans et al. (6) as well as an early review of discontinuation studies in the literature, which concluded that the point prevalence of persistent tardive dyskinesia (8%) was not much different than that of spontaneous dyskinesia (5%).

Despite our attempts to estimate incidences of tardive and spontaneous dyskinesias, there are many questions, including those raised by Dr. Quinn, that require further inquiry.

Involuntary Facial Movements, Not All Medication-Induced

SIR: An area of the article by Joanne D. Wojcik, R.N., M.S., C.S., and associates (1) that ought to raise concern is their report that of the 32 patients with tardive dystonia, at last evaluation as many as 18 had only facial movements (10 patients with blepharospasm and 14, grimacing). Such movements are commonplace and usually idiopathic (2, 3). Physicians should not automatically accept all involuntary facial movements as having been induced by medications, especially in this series where the medications were diverse in structure, and their administration preceded the development of the movements by more than 6 years in 11% of cases.

Moreover, whatever the cause, blepharospasm, more gen-

eralized involuntary facial movements (Meige's syndrome), hemifacial spasm, and spasmodic torticollis and related involuntary neck movements may now be treated with intramuscular injections of botulinum toxin (4). This novel therapy, although sometimes complicated by temporary muscle weakness and need for repeated injections about every 3 months, markedly reduces the involuntary movements without exposure to systemic side effects of previously reported medications, including tetrabenazine, clonazepam, bromocriptine, and anticholinergics, which have generally been ineffective. Botulinum toxin injections also hold promise for treatment of the classic, buccolingual form of tardive dyskinesia.

DAVID M. KAUFMAN, M.D.
Bronx, N.Y.

Dr. Cole and Associates Reply

SIR: We appreciate Dr. Kaufman's thoughtful reading of our paper, but do not concur with all his conclusions. In the absence of any basis for determining when blepharospasm is or is not idiopathic, its occurrence with other signs of dyskinesia in patients taking neuroleptics should be considered tardive dystonia.

The time from first neuroleptic treatment to onset of abnormal movements in our sample (over 6 years) is not at all unusual in nondystonic tardive dyskinesia and would therefore not make Meige's syndrome any more likely. Dr. Kaufman assumes that "diversity in structure" of the antipsychotics taken by our patients argues against their having the same disorder. So far, all dopamine blocking drugs, irrespective of structure, have been found to be associated with tardive dyskinesia. The common pharmacology seems more relevant than the actual chemical structure.

Botulinum toxin injections have provided marked benefit for patients with severe persistent dystonia of any etiology. However, its efficacy in lingual dystonia has been limited by dysphagia in nearly half the patients treated (1). Many patients with presumed tardive dystonia require maintenance antipsychotic treatment, and clozapine may help both the psychosis and the dystonia. To our knowledge, clozapine has not been tried in Meige's syndrome.

Antiglucocorticoid Effects of DHEA-S in Alzheimer's Disease

SIR: In an article by Owen M. Wolkowitz, M.D., and associates (1) the possibility of specific corticosteroid-related cognitive impairments is stressed. These authors speculate that anticorticoid hormonal treatment could ameliorate cognitive impairments associated with endogenous hypercortisolemia. Chronic glucocorticoid administration leads to hippocampal damage in the rat and, due to a dysfunction of the hypothalamic-pituitary-adrenal axis, to progressive dementia (2). Sunderland et al. (3) demonstrated reduced plasma concentrations of dehydroepiandrosterone-sulfate (DHEA-S) in Alzheimer's disease and discussed the possible importance of this hormone in the central nervous system. DHEA-S was shown to block enzymatic effects of glucocorticoids (4), thus, a certain part in the progression of Alzheimer's disease may be caused by the decrease of DHEA-S and its antiglucocorticoid functions.

In our own series, 24 drug-free patients with Alzheimer's disease (11 women, aged 58-86; 13 men, aged 62-88) and 50 normal control subjects (23 women, aged 18-81; 27 men, aged 21-81) were studied. Blood samples for DHEA-S (ng/ml) and cortisol (μ g/dl) plasma measurements were obtained after an overnight fast, stored at -20°C , and tested in the same assay by radioimmunoassay. The DHEA-S/cortisol ratio was calculated in all subjects studied. Data were analyzed by Wilcoxon's test. Diagnosis of Alzheimer's disease was established by DSM-III-R and confirmed by X-ray CT, excluding patients with multi-infarct dementia, and single photon emission computed tomography, tracing the parietotemporal hypoperfusion typical for Alzheimer's disease (5, 6). In patients with Alzheimer's disease, routine laboratory tests, vitamin B₁₂, folic acid, and T₃, T₄, and thyrotropin serum levels were within normal limits.

A strong negative correlation was found between age and DHEA-S ($r=-0.8$ for women and $r=-0.7$ for men) (4, 5), but no significant correlation was found between cortisol levels and age, therefore, the DHEA-S/cortisol ratio dropped remarkably in older normal subjects (older than 60 years old) as compared to young individuals (45 years of age or younger) ($p<0.01$). Interestingly, a trend was found for a lower DHEA-S/cortisol ratio in Alzheimer's disease patients compared to age- and sex-matched control subjects ($p<0.1$), indicating that this ratio could be an appropriate measure for the effects of DHEA-S as an antiglucocorticoid by which subjects at risk for the neurotoxic effects of glucocorticoids could be identified (6). These previous results suggest a possible relation of cognitive impairment to circulating corticoid levels, as mentioned by Dr. Wolkowitz and colleagues (1), and they indicate a possible role of DHEA-S in diminishing cortisol effects on hippocampal cells avoiding progressive hippocampal degeneration in Alzheimer's disease (6).

Dr. Wolkowitz and Associates Reply

SIR: We have previously reported that increased circulating corticosteroid levels may be associated with cognitive impairment in certain conditions. Dr. Friedrich Leblhuber, M.D., and colleagues suggest that levels of other steroid hormones such as dehydroepiandrosterone (DHEA) and DHEA-S may also be relevant in determining cognitive performance since such hormones may have "antiglucocorticoid" effects. We agree with their suggestion that examination of cortisol/DHEA-S ratios may be more informative than examination of levels of either hormone individually.

While the nature of possible antiglucocorticoid effects is unknown, several authors have reported physiological antagonism by DHEA of corticosteroid effects such as thymic involution and suppression of lymphocyte proliferation (1-4). We propose that, in addition to such "pharmacodynamic" effects, DHEA may have a "pharmacokinetic" effect on circulating cortisol levels. We have begun a preliminary, open-label study examining the possible antidepressant and cognition-enhancing effects of orally administered DHEA, 30-90 mg/day, in patients with major depressive illness who have low baseline DHEA or DHEA-S levels. One interesting preliminary finding to emerge from this study is that pharmacologically induced increases in DHEA levels (resulting in normalized age-corrected levels) are significantly correlated with decreases in 4:00 p.m. serum cortisol levels ($r = -0.78$, $df = 5$, $p < 0.04$). This finding, if replicated in larger-scale studies, would indicate that DHEA may indeed have "antiglucocorticoid" effects, perhaps through a "pharmacokinetic" action. Prior studies have suggested that DHEA sulfuric ester may decrease pituitary ACTH release in rats (4), and that DHEA may inhibit various enzymatic activities (5) also resulting in decreased cortisol biosynthesis. These findings raise the possibility that DHEA administration may have salutary effects in ameliorating corticosteroid-associated behavioral and cognitive impairment in certain patients.

An additional approach, involving the administration of precursor steroid hormones, has also been recently proposed. The biosynthesis of steroid hormones begins with cholesterol, from which the glucocorticoids, mineralocorticoids, and sex steroids all derive. Pregnenolone, a key cholesterol metabolite, is the major precursor for the steroid hormones. Its formation, regulated by pituitary hormones, may become rate-limiting in aging, stress, and other conditions, resulting in steroid imbalances. The recent findings of a striking memory-enhancing effect of pregnenolone and literature showing virtually no human toxicity, suggest that administration of pregnenolone

may help reestablish normal relations among the various steroids when abnormalities occur. We are proceeding with investigations to test these hypotheses in patients with depression and Alzheimer's disease.

Credibility of Patients in Psychiatric Research

SIR: I must agree with the criticism by F. Wayne Furlong, M.D. (1), that the methods used by Barbara Sanders, Ph.D., and Marina H. Giolas, M.D. (2, 3), and, in particular, by George R. Brown, M.D., and Bradley Anderson, M.D. (4, 5), may have resulted in false or exaggerated reports of childhood abuse. Although the latter two authors replied that they exercised great care to guard against this, the very nature of their paradigm suggests otherwise. The interviewers directly asked psychiatric patients about abusive experiences and would repeat these questions if an affirmative response was not at first obtained. The potential for demand characteristics with such explicit questioning procedures is obvious and would be a problem even with normal subjects.

I would also like to comment on the reply by Dr. Sanders (2) that "for any verbal report measure, what we know depends on how willing we are to believe our subjects." I fail to see how holding private reservations about the accuracy of an abuse memory necessarily implies "discrediting the witness." I also fail to see how believing all such memories to be accurate is somehow a "more parsimonious" approach, especially when belief in some memories requires acceptance of such nonparsimonious constructs as repression and dissociation. Finally, I take issue with Dr. Sanders' statement that high dissociating subjects, because they have greater pain tolerance, would therefore tend to minimize rather than exaggerate reports of abuse. One could just as easily argue that their ability to tolerate aversive stimulation enables them to uncover (or confabulate) more severe memories of abuse. The problem here is that one can always find some piece of evidence that can be twisted to defend virtually any position. Such loose conceptualizing will do little to advance our understanding of the issue.

Contrary to Dr. Sanders' opinion, what we know depends

not on belief but rather on our willingness to critically challenge our assumptions and to entertain alternative explanations. For example, DeGree and Snyder (6) have shown that subjects placed in ego-threatening situations are then more likely to report traumatic life events. They interpret these results as possibly indicating an attempt by subjects to provide justification for potential failure. Could a similar effect play a role in altering abuse memories reported by psychiatric patients? Such a line of investigation might prove more fruitful than further correlational studies based upon largely unsubstantiated, and essentially nonfalsifiable, self-reports.

RUSSELL A. POWELL, PH.D.
Edmonton, Alta., Canada

Dr. Sanders Replies

SIR: The issue Dr. Powell addresses is an important one, and I welcome the opportunity his comments afford to expand my reply to Dr. Furlong. For clarity, I will restrict my remarks to questions concerning my own paper and will not comment on the work of Drs. Brown and Anderson.

What is to be explained in our research is the significant correlation in disturbed adolescents between the degree of dissociation and the degree of recalled childhood stress or trauma. The relationship was positive, that is, higher dissociators reported higher levels of childhood stress. This correlation cannot be dismissed simply by proposing that high dissociators are "unreliable" in reporting or remembering their childhoods, since mere unreliability, with some subjects overestimating and others underestimating the degree of trauma they had experienced, would not produce a relationship between dissociation and childhood experience.

To account for the correlation as an artifact of memory or reporting, one must propose that high dissociators, as a group, are biased in reporting or remembering the past. More specifically, since the correlation was a positive one, one must propose that high dissociators *overestimate* the stressfulness of their childhoods, as Dr. Powell suggests they might. I agree with Dr. Powell that such a position could be defended, given our present state of knowledge; however, as he indicates, in my earlier remarks I presented some evidence for the opposite bias, i.e., that high dissociators might *underestimate* the degree of trauma they had experienced. This bit of data on the other side of the argument simply indicates our inability to resolve this issue on the basis of existing empirical evidence.

When it comes to speculation concerning the direction of any hypothesized bias, I heartily agree that we can "defend virtually any position."

An important alternative is that dissociation level is linked to any particular childhood reporting bias, but that high dissociators have indeed experienced more traumatic childhoods than low dissociators. This is the alternative I called "parsimonious." I regard it as parsimonious because it fits with a variety of types of evidence suggesting that trauma produces dissociation. We know, for example, that acute trauma may precipitate dissociative experiences, and also that individuals suffering from dissociative disorders very frequently report extremely traumatic episodes earlier in life or in childhood.

In suggesting that we not "discredit the witness," I am asking that we investigate the reliability of these reports rather than simply dismiss them. My argument is that we should not prejudge the issue by assuming that our subjects' memories are distorted or biased. I do not, of course, advocate the uncritical acceptance of self-reports, rather I warn against their uncritical rejection. What is needed is not more speculation, but more study.

BARBARA SANDERS, PH.D.
Storrs, Conn.

Recovery and Shorter Duration of Hospitalization

SIR: In reading the recent article by Gabor I. Keitner, M.D., and associates (1), I wondered why the authors did not consider that two of the five factors most strongly associated with recovery might be related to each other. I am referring to the shorter duration of hospitalization and the absence of more than two previous episodes of hospitalization in the recovered subset of patients. One possible explanation for the finding that less time in hospitals is associated with recovery is that hospitalization itself may contribute to the pattern of morbidity.

Both community psychiatry and its predecessor, military psychiatry, have emphasized the wisdom of treating the patient within his or her life context as close to the scene of trauma as possible and for as brief a time as is necessary for stabilization. In my experience in the military during the Vietnam war, I was taught that the likelihood of rapid recovery diminished considerably when the patient was hospitalized and/or evacuated. Although there is need for hospitalization in some patients with major depression, HMOs and other managed care systems, with their emphasis on outpatient alternatives, have taught us that it is often possible to avoid this major step without compromising care. This article suggests it may be preferable.

It may be speculated that it is not the pattern of recurrent depression or its severity alone that determine morbidity, that the manner and intensity of treatment may be a major determining factor as well. Since neither the recovered nor unrecovered patients were treated with ambulatory alternatives or even particularly brief hospitalization, it would be important to compare these options with traditional, 2- to 3-week inpatient stays. It may very well be that hospitalization, when necessary, involves a kind of "therapeutic window," and that more concerted efforts should be made to avoid it when possible, and to keep it brief when it is unavoidable. If validated, this hypothesis would bring synergy to our sometimes divergent concerns with cost and quality of care.

MICHAEL J. BENNETT, M.D.
Belmont, Mass.

Dr. Keitner and Associates Reply

SIR: The hypothesis advanced in Dr. Bennett's letter, namely, that hospitalization itself may contribute to morbidity in affective disorder, may be important to test. Our study, however, does not in any way address this issue. More specifically, we do not have data to suggest that avoiding hospitalization is necessarily "preferable."

We noted in our article that "correlation between length of hospital stay and the other variables in the model were neither substantial nor significant." Nonetheless, the technique of log

linear analysis takes into account correlations between variables entered into the model.

We would be cautious about drawing an analogy between the treatment of the sequelae of acute traumatic experiences as in war and the treatment of major depression which may have no relationship to preceding traumatic events. It should also be noted that most of our patients were, in fact, treated unsuccessfully with "ambulatory alternatives."

Although it may well be true that a "therapeutic window" for a successful hospital stay exists, we do not yet know what that window is. At the least, we suspect that this window is likely to be different for different patients depending on the nature of their depressive illness, comorbidity, psychological make-up, and social resources. Although overly prolonged hospitalization may lead to potential problems, so may unduly short hospitalizations.

Corrections

In the article "An Empirical Evaluation of the Global Deterioration Scale for Staging Alzheimer's Disease" by Carl Eisdorfer, Ph.D., M.D., et al. (February 1992, pp. 190-194), on p. 192, second paragraph, seventh line, the words "dependent variables" should be substituted for "independent variables."

The authors of the letter "Clozapine-Induced Priapism" (Joseph Ziegler, M.D., and David Behar, M.D., February 1992, pp. 272-273) thank Dr. Richard Balon for correcting the references. Reference 2 should read "Balon R, Berchou R, Han H: Priapism associated with thiothixene, chlorpromazine, and thioridazine (letter). J Clin Psychiatry 1987; 48:216." In reference 3 also, the journal is J Clin Psychiatry.

In the article "Alprazolam as a Neuroleptic Adjunct in the Emergency Treatment of Schizophrenia" by James G. Barbee, M.D., et al. (April 1992, pp. 506-510), the unit of measurement for alprazolam and haloperidol blood levels described in the fifth paragraph of the second column on p. 508 should be "ng/ml."

In the article "Symptom Responses of Female Vietnam Veterans to Operation Desert Storm" by Jessica Wolfe, Ph.D., et al. (May 1992, pp. 676-679), on p. 678 the key to figure 1 is inverted. The corrected figure follows.

FIGURE 1. Mean SCL-90-R Scores During Operation Desert Storm for Female Vietnam Veterans Grouped by Scores on the Mississippi Scale for Combat-Related Posttraumatic Stress Disorder

1991-1992 Annual Report of the American Board of Psychiatry and Neurology, Inc.

COMPOSITION OF THE BOARD

At its business meeting in July 1991, the American Board of Psychiatry and Neurology (ABPN) elected the following officers, who began their terms on Jan. 1, 1992: Dr. Gary J. Tucker, President; Dr. Stuart A. Schneck, Vice-President; Dr. James H. Shore, Secretary; Dr. Ludwig Gutmann, Treasurer; and Dr. Lenore C. Terr, Executive Committee Member-at-Large.

Dr. Sheldon Miller (psychiatrist, Chicago), nominated by the American Medical Association, was elected to a 4-year term on the board to succeed Dr. Maurice J. Martin, who completed his second 4-year term on Dec. 31, 1991. Dr. Darryl C. De Vivo (neurologist, New York), nominated by the American Neurological Association, was elected to a 4-year term on the board to succeed Dr. William E. Bell, who completed his second 4-year term on Dec. 31, 1991. Dr. Lenore C. Terr (psychiatrist, San Francisco) was renominated and reelected to serve a second 4-year term as a director. Dr. Michael P. McQuillen (neurologist, Lexington, Ky.) was renominated for a second term of 4 years after completing a first term of 1 year. The names of the 1992 ABPN directors follow; those serving second 4-year terms are not eligible for reelection.

From the American Medical Association—psychiatry directors: Dr. Kenneth Z. Altshuler (first term expires Dec. 31, 1992), Dr. Sheldon I. Miller (first term expires Dec. 31, 1995), and Dr. Peter M. Silberfarb (first term expires Dec. 31, 1994).

From the American Psychiatric Association—psychiatry directors: Dr. William T. McKinney (first term expires Dec. 31, 1994), Dr. James H. Shore (second term expires Dec. 31, 1994), Dr. Peter E. Tanguay (first term expires Dec. 31, 1993), Dr. Lenore C. Terr (second term expires Dec. 31, 1995), and Dr. Gary J. Tucker (second term expires Dec. 31, 1992).

From the American Neurological Association—neurology directors: Dr. Darryl C. De Vivo (first term expires Dec. 31, 1995), Dr. J. Donald Easton (second term expires Dec. 31, 1992), Dr. Ludwig Gutmann (second term expires Dec. 31, 1994), and Dr. Stuart A. Schneck (second term expires Dec. 31, 1993).

From the American Academy of Neurology—neurology directors: Dr. Mark L. Dyken (first term expires Dec. 31, 1992), Dr. Marvin A. Fishman (first term expires Dec. 31, 1993), Dr. Michael P. McQuillen (second term expires Dec. 31, 1995), and Dr. Burton A. Sandok (first term expires Dec. 31, 1994).

Dr. Stephen C. Scheiber is the Executive Vice President of the ABPN.

EXAMINATIONS

Part I

At the part I (written) examination on March 31, 1992, 2,974 psychiatrists were examined; 1,788 (60%) passed and 1,186 (40%) failed. A total of 775 neurologists were examined; 431 (56%) passed and 344 (44%) failed. A total of 113 child neurologists were examined; 60 (53%) passed and 53 (47%) failed. Table 1 contains the

numbers of candidates in each year from 1987 to 1992. The next part I examination will be held on March 30, 1993. Applications for that examination are due no later than Sept. 1, 1992, and are available from the American Board of Psychiatry and Neurology, Inc., 500 Lake Cook Rd., Suite 335, Deerfield, IL 60015.

Added Qualifications in Geriatric Psychiatry

At the second geriatric psychiatry (written) examination, on March 31, 1992, 578 geriatric psychiatrists were examined; 359 (62%) passed and 219 (38%) failed. There will not be a geriatric psychiatry examination in 1993. It is anticipated that the next geriatric psychiatry examination will be held in 1994.

Added Qualifications in Clinical Neurophysiology

At the first clinical neurophysiology (written) examination, on March 31, 1992, 278 clinical neurophysiologists were examined; 227 (82%) passed and 51 (18%) failed. Of those totals, four who passed and one who failed have primary certification in psychiatry; the remaining individuals have primary certification in neurology or neurology with special qualification in child neurology. There will not be a clinical neurophysiology examination in 1993. It is anticipated that the next clinical neurophysiology examination will be held in 1994.

Added Qualifications in Addiction Psychiatry

The first examination for added qualifications in addiction psychiatry will be held in concert with the next part I examination, to be held on March 30, 1993. Applications for that examination are due no later than Sept. 1, 1992, and are available from the American Board of Psychiatry and Neurology, Inc., 500 Lake Cook Rd., Suite 335, Deerfield, IL 60015. It will be held at the same sites as the part I examination and will be approximately 3½ hours long. This will be a multiple-choice written examination. The ABPN anticipates administering this examination on average once every 2 years.

Part II

At the 1991 part II (oral) examinations held in Los Angeles (Jan. 13-15), New Orleans (April 14-16), and Philadelphia (Oct. 27-29), 1,881 psychiatrists, 420 neurologists, and 72 child neurologists were examined. For statistics on these examinations, refer to table 2. The examination sites for 1992 are Atlanta (Jan. 10-12), San Antonio, Tex. (April 5-7), San Francisco (June 14-16), and New York (Nov. 15-17).

The current fees for examination are as follows: application fee=\$300, part I examination fee (submitted with the application fee)=\$300, part I reexamination fee=\$300, part II examination fee=\$600, part II reexamination fee (for psychiatry candidates, failure of major; for neurology candidates, failure of major or failure of major and minor)=\$600, part II reexamination fee (for neurology candi-

dates, failure of minor)=\$400, added qualifications application fee=\$300, added qualifications examination fee (submitted with the application fee)=\$500, added qualifications reexamination fee=\$500.

BOARD DECISIONS AND ITEMS OF INTEREST

1. The American Board of Medical Specialties approved the application of the ABPN for certification for added qualifications in addiction psychiatry at its September 1991 meeting. The Committee on Certification for Added Qualifications in Addiction Psychiatry was appointed in October 1991 and held its first meeting in December 1991. For 1992 the committee membership includes Dr. Sheldon Miller, Chair (ABPN psychiatry director, Chicago); Dr. Marc Galanter, Vice-Chair (New York); Dr. Richard Frances (Newark, N.J.); Dr. Edward Kaufman (Orange, Calif.); Dr. Edward Khantzian (Haverhill, Mass.); Dr. Thomas Kosten (New Haven, Conn.); Dr. Collins Lewis (St. Louis); Dr. Edgar Nace (Dallas); Dr. George Woody (Philadelphia); and Dr. Roger Walker (Seattle).

The general requirements for added qualifications in addiction psychiatry are as follows. The candidate must be certified by the ABPN in psychiatry. All licensing and training requirements must be met before the application for examination is submitted. A formal application on the original form must be completed and filed with supporting documentation and fees by the deadline; a photocopy of the application will not be accepted. A certificate will be issued for a 10-year time-limited period, after which recertification will be necessary to maintain active certification. The training requirements are as follows. The applicant must have completed a 1-year fellowship in addiction psychiatry in a program approved by the Accreditation Council for Graduate Medical Education (ACGME), beginning no sooner than postgraduate year 5. For the first 5 years admission to examination may be achieved by completing a 1-year fellowship in an addiction psychiatry program that is clearly identified as a U.S. or Canadian program. For the first 5 years admission to examination may also be achieved by spending 25% of practice time treating addiction psychiatry patients. The 1 year of specialized training in addiction psychiatry may be completed on a part-time basis provided it is not less than half-time and is taken at one center.

2. During its July 1991 meeting the ABPN held a conference focusing on recertification. Speakers from other boards of the American Board of Medical Specialties participated and provided useful information. The psychiatry and neurology directors of the ABPN agree that the recertification examinations will be cognitive examinations. It was reaffirmed that the recertification examination given by the ABPN will not be offered to any individual who has not been certified by the ABPN.

A meeting to discuss recertification in psychiatry was held in April 1992. The participants were the ABPN psychiatry directors and representatives from the American Psychiatric Association (APA), the American Academy of Child and Adolescent Psychiatry, the ABPN Committee on Certification in Child and Adolescent Psychiatry, the ABPN Committee on Certification for Added Qualifications in Geriatric Psychiatry, and the ABPN Committee on Certification for Added Qualifications in Addiction Psychiatry. The meeting focused on education and the examination process and format.

3. The ABPN reaffirmed its policy whereby all licensing and training requirements must be met before application for examination. An

Reexaminees	19	16	84	3	16

exception is made for residents who complete training after Sept. 1 but before Oct. 1.

4. The ABPN determined that in 1994 there will be two part I (written) examinations, one in March or April and one in October. Effective in 1995 the ABPN will begin administering the part I examination in October instead of in the spring. This is being done in an effort to accommodate residents who wish to take the ABPN certification examinations closer to completion of residency training. The deadline for submitting applications for the spring 1994 examination will be Sept. 1, 1993, and the tentative deadline for applications for the October 1994 examination is Feb. 1, 1994. To be certain of the actual deadline date, individuals should contact the ABPN office and look for announcements in medical journals.

5. The ABPN reaffirmed its policy that every applicant must have an *unlimited* license to practice medicine in a state, commonwealth, territory, or possession of the United States or a province of Canada. At the time of application every applicant is required to submit copies of a current license registration with the expiration date noted, in addition to documentation of all training, photographs, and fees.

6. The documentation of completion of training must specify the exact dates of training. If the documentation is in the form of a letter, the letter must be signed by the training director or chairperson of the program.

7. The ABPN adopted a policy allowing individuals to have more than one application on file simultaneously. It is the applicant's responsibility to contact the ABPN office to avoid possible conflicts in examination scheduling.

8. The ABPN adopted the following policy regarding leave or vacation time during residency training. Leave or vacation time may not be used to reduce the total amount of required residency training or to make up deficiencies in training. The ABPN does not have a policy regarding the amount of leave or vacation time allowed, as each program may develop individual leave or vacation time for the resident in accordance with the overall institutional policy.

9. The ABPN voted that for individuals entering residency training as of July 1, 1994, who are seeking certification in neurology, an acceptable alternative to a full year of internal medicine is a full year in which a minimum of 6 months of training is in internal medicine, and these 6 months cannot include rotations in neurology or emergency medicine. At least 2 of the additional 6 months must be spent in pediatrics and/or emergency medicine. No more than 2 of the remaining 4 months may be spent in neurology.

10. The ABPN voted that for individuals seeking certification in neurology with special qualification in child neurology who are already certified in neurology, no more than 3 months of child neurology training from an adult residency can be credited toward the 12-month additional child neurology requirement during training in an ACGME-approved child neurology residency training program. Nine additional months of child neurology residency training would be needed in a program approved by the ACGME or the Royal College of Physicians (Canada) [RCP(CN)]. In addition, 1 year of general pe-

Pass	35	50
Fail, must reapply	35	50

diatric training in an ACGME- or RCP(CN)-approved program is required.

11. The ABPN voted that individuals seeking certification in neurology with special qualification in child neurology who enter training as of July 1, 1992, may complete the following training for 2 of the 5 years of training: 1 year of training in general pediatrics and 1 year of research in the basic neurosciences. The basic neuroscience pathway was created as an alternative track for residents who are planning a research career in academic child neurology. The year of basic neurosciences would provide training in a research discipline related to child neurology and is intended to increase the trainee's knowledge and ability to compete for federal and nonfederal grant support. The trainee must spend at least 80% of his or her time in basic neurosciences during this year of training. For the purpose of this training track, "basic neurosciences" is defined as laboratory research related to the cellular or molecular basis of neurological diseases. Examples of relevant basic disciplines include molecular neurogenetics, neurochemistry, neuropharmacology, neurophysiology, neuroanatomy, neuroimmunology, developmental neurobiology, biophysics, and cell biology. This track of training must be approved before completion of the total 5 years of training.

12. The ABPN will be reviewing information at its July 1992 meeting in consideration of whether the experimental pediatrics-psychiatry joint training program should become a permanent training track.

13. The ABPN voted to proceed with consideration of offering an examination for certification in forensic psychiatry. A letter of intent and application have been sent to the American Board of Medical Specialties. This should be reviewed and approved no earlier than September 1992, and the earliest time an examination could be administered would be in 1994.

14. The ABPN and the American Board of Physical Medicine and Rehabilitation have established guidelines for combined residency training in neurology and physical medicine/rehabilitation. The guidelines are available from the ABPN office.

15. The ABPN and the American Board of Internal Medicine have established guidelines for combined residency training in neurology and internal medicine. The guidelines are available from the ABPN office.

16. The ABPN and the American Board of Internal Medicine have established guidelines for combined residency training in psychiatry and internal medicine. The guidelines are available from the ABPN office.

17. In conjunction with its summer 1992 policy meeting, the ABPN will be holding a retreat that will consist of two debates focusing on subspecialization and the oral examination.

18. At the 1991 APA annual meeting, the ABPN offered a work-

shop on subspecialization. The ABPN psychiatry directors presented information and responded to questions. In addition, the ABPN Executive Vice President and psychiatry directors continue to participate in plenary sessions and other workshops of APA and the American Association of Directors of Psychiatric Residency Training in an attempt to clarify information and to publicize current issues of interest. A workshop was held at the 1992 APA annual meeting focusing on recertification.

19. At the fall 1991 meeting of the American Neurological Association and the spring 1992 meeting of the American Academy of Neurology, ABPN neurology directors and the Executive Vice President met with the Association of University Professors of Neurology to discuss current issues of the ABPN and to respond to questions. These meetings prove valuable in outlining the ABPN's current policies, training requirements, and other items of interest.

COMMITTEE ON CERTIFICATION IN CHILD AND ADOLESCENT PSYCHIATRY

At its business meeting in February 1991, the Committee on Certification in Child and Adolescent Psychiatry elected the following officers, who began their terms on Jan. 1, 1992: Dr. Theodore Shapiro, Chair; Dr. Thomas M. Haizlip, Vice-Chair; Dr. Lois T. Flaherty, Secretary-Treasurer.

Dr. Elizabeth Weller (Columbus, Ohio) was elected to a 6-year term effective Jan. 1, 1993, to succeed Dr. William H. Sack, who completes his 6-year term on the committee on Dec. 31, 1992.

Members of the Committee on Certification in Child and Adolescent Psychiatry are elected to serve one 6-year term each and are not eligible for reelection. The members of the 1992 committee are Dr. Walter R. Anyan, Jr. (representative from the American Board of Pediatrics; term expires Dec. 31, 1994), Dr. Mark J. Blotcky (term expires Dec. 31, 1997), Dr. Lois T. Flaherty (term expires Dec. 31, 1993), Dr. Thomas M. Haizlip (term expires Dec. 31, 1995), Dr. Kenneth S. Robson (term expires Dec. 31, 1994), Dr. William H. Sack (term expires Dec. 31, 1992), and Dr. Theodore Shapiro (term expires Dec. 31, 1993).

Examination

At its Sept. 20-22, 1991, examination in Baltimore, the Committee on Certification in Child and Adolescent Psychiatry examined 342 candidates; 205 (60%) passed, 58 (18%) conditioned, and 79 (22%) failed or failed/must reapply. Additional statistics are given in table 3. The 1992 examination will be held Sept. 11-13, 1992, in Chicago. The 1993 examination will be held Sept. 10-12, 1993, in Raleigh-Durham, N.C. Applications are due by the May 1 preceding the examination and are available from the American Board of Psychiatry and Neurology, Inc., 500 Lake Cook Rd., Suite 335, Deerfield, IL 60015.

The current fees for examination are as follows: application fee=\$300, oral examination fee=\$600, oral reexamination fee (condition)= \$400, oral reexamination fee (failure)= \$600, written examination or reexamination fee=\$300.

With their applications applicants are required to submit copies of current license registrations showing expiration date, in addition to documentation of all training, photographs, and fees. Training documents must include the exact dates of training. All licensing and training requirements must be met before application for examination.

Committee Decisions and Items of Interest

1. The committee is exploring formats for the recertification examination.

2. The committee continues to arrange examinations following the weekend format. This format has been well received by the host facilities and an overwhelming majority of candidates and examiners.

3. The committee continues to note difficulties with certificates issued to residents. If child psychiatry training is done during general residency, it must be designated as such.

Presidential Address: Reflections on Humane Values and Biopsychosocial Integration

Lawrence Hartmann, M.D.

To realize the relative validity of one's convictions, and yet stand for them unflinchingly, is what distinguishes a civilized man from a barbarian.

—Alexander Herzen, quoted by Isaiah Berlin (1)

It is an honor to be APA president and to address you all. It is a pleasure to be surrounded by family and friends and colleagues. Many of you have helped me, inspired me, challenged me, given me pleasure, given me strength, and taught me, in countless ways over many years, and I am very grateful.

I have had an exciting year. But then, reading and hearing past addresses by APA presidents suggest that many years are exciting. There is continuity and development, but also adventure and individuality and play, in APA psychiatry, as well as in APA presidents.

I hope there has been some adventure, individuality, and play in my presidency, and I hope there may be some in this opening session speech; and that of my distinguished successor, Dr. English.

People sometimes ask me about the relationship of APA presidents to their immediate predecessors, and to their immediate successors, and to the APA medical director (the medical director stays, some of us have noticed, while presidents come and go); also to the Speaker of the APA Assembly, to the members of the Board of Trustees, and to APA senior staff. There are opportunities for covert and overt power struggles, rivalry, narcissistic assertiveness, and corrective overcompensations. There are possibilities for blandly dissolving into a group. But there are also opportunities

for friendship, and fun, and stimulating interaction and cooperation—and I am pleased that from my point of view, Drs. English, Sabshin, Benedek, Pfaehler, Robinson, and other current leading APA figures, have been stimulating friends. We have shared major goals and values, have not often felt bad about our real disagreements, and—I think—have enjoyed working together.

One of my pleasures in getting to know Dr. English a bit this year has been in learning from him, and noticing that the fact that he and I are different, in many details, has added interest to my admiration of his cheerful intelligence, his political and economic and organizational experience, his energy, and his commitment to psychiatry.

I hope and expect Dr. English will avoid something I have noticed in myself: a tendency toward a neurosis (not in *DSM-III-R*, of course) specifically designed for the president of APA: I have noticed in myself a frequent idea that a) I am supposed to know all of psychiatry, and b) I am supposed to fix all of psychiatry. Despite reality testing, I have felt guilt now and then that I have fallen so far short at both impossible tasks.

It is quite clear that no one can know all of psychiatry, and no one can fix all of psychiatry—but such tasks can be instructive, and may teach us not just humility, but realism. How much knowledge of biopsychosocial psychiatry do we require of ourselves and our trainees? What solid core of knowledge and experience allows us to respect what variety among ourselves? What is enough to *know*, in this age of subspecialization, booming biology, intrusive economics, subtle psychodynamics, and out-of-control social arrangements? And what is enough for each of us to *do* to try to make things better, for psychiatry and for mental health, and against mental illness?

This is not a happy era for much of psychiatry. It is a good era for brain research, and a hopeful era for psychopharmacology, but a troublesome era for clinicians, for a great many patients, and for public and private funding. In the state where I live, for instance, under the short-term flag of saving money, the state has been re-

Presented at the 145th annual meeting of the American Psychiatric Association, Washington, D.C., May 2–7, 1992. Dr. Hartmann, 120th President of the American Psychiatric Association, is in the private practice of adult, adolescent, and child psychiatry in Cambridge, Mass., and is on the faculty of Harvard Medical School. Address reprint requests to Dr. Hartmann, 147 Brattle St., Cambridge, MA 02138.

Copyright © 1992 American Psychiatric Association.

peatedly slicing away mental health funding and service. It is also a tough era for the use of the biopsychosocial model, which is the difficult but solidest scientific model for our field.

It is a challenging era, and APA has worked hard on thousands of issues this year. I have tried to help on many.

In this speech, I will not summarize our era, or even this past year, or even this past year in APA. I will mention a few issues, problems, challenges, and changes; I will repeat, or vary, several of my last year's themes; and I will have as an underpinning of my talk, and relevant to every economic and psychodynamic and molecular biological corner of my talk, my continuing presidential theme: *humane values and biopsychosocial integration*.

E.B. White advised writers to be clear, and not to be afraid of repetition. I sometimes try to follow his advice when offering my presidential theme.

I will start by calling, or recalling, your attention to several papers by George Engel in various medical and scientific journals, mostly in the late 1970s. He says important things well, and is still continually relevant to our field (perhaps in some ways, he is even *more* relevant to psychiatry today). Also, in talking about integrated psychiatry, we ought continually to integrate our past. Adding new data is essential, and often exciting. But just adding data is not enough. We need concepts, and we need integration.

Dr. Engel of Rochester was a major voice—perhaps *the* major voice—a few years ago, saying that the usual biomedical model is inadequate, and that we need a biopsychosocial model. His examples were largely medical rather than specifically psychiatric. His longest case example was an acute myocardial infarction, with a cardiac arrest; in that case, as in others, he demonstrated the efficient relevance of the psychological, the psychodynamic, and the social, to what was, and often is, seen and treated more partially, and narrowly, as one or another physiological disorder.

Engel, in his papers, sees medicine in the 1960s, 1970s, and 1980s, as not biopsychosocial enough, but says that *psychiatry* is relatively good at being biopsychosocial. I worry, as you will notice, that in 1992 even psychiatry is not biopsychosocial enough. In fact, I think psychiatry has regressed from what was a fairly sound, overall biopsychosocial model. Partly because of biological advances—e.g., in neurobiology, psychopharmacology, molecular genetics—psychiatry is in many ways *less* biopsychosocial than it was 20 years ago. As part of neurobiological advances, and the remedicalization of psychiatry—very productive in some spheres—psychiatry and the model psychiatry has of illness and wellness have, it seems to me, shrunk back from biopsychosocial integration toward the narrower, more purely physiological medical model that George Engel persuasively argued was inadequate for all of medicine 15 or 20 years ago.

"The rest of medicine," said Dr. Engel (2), "appears neat and tidy. It has a firm base in the biological sci-

ences, enormous technological resources at its command, and a record of astonishing achievement in elucidating mechanisms of disease, and devising new treatments. It would seem that psychiatry would do well to emulate its sister medical disciplines, by finally embracing once and for all the medical model of disease.

"But I do not accept such a premise," Engel added, "rather, I contend that all medicine is in crisis . . . from the same basic fault as psychiatry's, namely adherence to a model of disease no longer adequate for the scientific tasks and social responsibilities of either medicine or psychiatry.

"The dominant model of disease is *biomedical*, with molecular biology its basic scientific discipline. It assumes disease to be fully accounted for by deviations from the norm of measurable biological (somatic) variables. It leaves no room within its framework for the social, psychological, and behavioral dimensions of illness" (2, pp. 129–130).

Engel (3) said that "Rasmussen traces the philosophic origins of this [the biomedical] model back three or four centuries when established Christian orthodoxy lifted the prohibition against physicians dissecting the human body as long as they did not presume to deal with man's soul, morals, mind, and behavior This compact helped determine that Western Medicine be based upon dualism and reductionism Dualism predicates separation of mind from body. Reductionism assumes that the understanding of a more complex entity can be best achieved by its analysis into its component parts and therefore that the complexities of life and biological phenomena, including behavior and mental processes, are to be studied and explained by the methods and in the language of physics and chemistry. Reductionism fosters a view of nature as involving interactions of discrete entities in a linear causal fashion, simple cause-and-effect relationships. This influence is expressed in the habit of speaking of diseases not as dynamic processes but as discrete entities, the elimination of which awaits only discovery of their causes" (3, pp. 156–157).

"The biomedical model," said Engel, "has been extraordinarily fruitful. But this very success has served not only to entrench dualism and reductionism but also to encourage its more enthusiastic advocates to promote the biomedical model as ultimately capable of explaining all aspects of health and disease. The dogmatism inherent in such blind faith in and exaggerated claims for the model has been a powerful factor in deflecting scientific interest and attention from problems that do not readily yield to the biomedical approach. Outstanding among these have been the more personal, human, psychological, and social aspects of health and disease" (3, p. 157).

"Nothing exists in isolation. Whether a cell or a person, every system is influenced by the configuration of the systems of which each is a part, that is, by its environment Neither the cell nor the person can be fully characterized as a dynamic system without characterizing the larger system . . . of which it is a part" (4, p. 537).

Engel points out that some shifting from the biomedical to the biopsychosocial model *has* been successfully tried now and then, as prominently at Hopkins at the time of Adolf Meyer, and at Rochester more recently.

"The biomedical model is disease oriented" but "not patient oriented," said Dr. Engel (3, p. 158).

That is true. It is even convenient. But I would argue that particularly in the area of psychiatry, the biomedical model is usually not even fully or competently disease oriented.

I think much of George Engel's writing on medical models is pointedly relevant today, to good clinical care, good service delivery and planning, good teaching, good research, good prevention, and good long-term politics and economics.

Yet, Dr. Engel's point of view has formidable opponents in the political and economic forces in and around psychiatry today, and in many who like and respect and do biological psychiatry.

We psychiatrists, with our recent and continuing excellent but unbalancing advances in brain biology, and with our influential shift toward the relatively superficial and undynamic *DSM-III* and *DSM-III-R*, would do well to take Dr. Engel to heart.

Before going on to a few words about *humane values*, and about new science; splitting of psychiatry; managed care; universal access; human rights; children and adolescents; and a few other issues—before all that, let me add an example of new scientific research that I think may help some of us think biopsychosocially. Last year, in my president-elect's speech, I used the *clinical* example of a child patient who had diagnostic and therapeutic issues that demanded simultaneous thought and therapeutic action in biological, psychological, and social fronts. Less would have been bad psychiatry. There are thousands of patients I could point to as lively parallel examples. In fact, *all* patients I have ever seen seem to me best looked at biopsychosocially, even if likely strategies for understanding and helping one may be more in one realm, for another, more in another. All patients—an abused child, a drug-abusing teenager, a neurotic graduate student, a schizophrenic adult, a depressed elder, an AIDS patient, a homeless patient—all patients deserve integrated biopsychosocial understanding and help.

But that is human patients. Here, briefly, to make a biopsychosocial integration point, I want to compare you all to . . . aggressive fish.

You may wish to resist the comparison, or you may not. And I apologize that the following research was done only on male fish. I expect that there are, or soon will be, comparable studies on females.

Dr. Russell Fernald, a Stanford neurobiologist, has been studying the African cichlid fish. He has discovered that how a male cichlid interacts with other males, and whether it is socially dominant or meek, not only has a major effect on the fish, but *changes the brain cells* in charge of the fish's size, color, and capacity to reproduce.

In aggressive male fish, commanding large territory, brain cells in the hypothalamus are six times larger than

are equivalent cells in milder mannered males. Further, the dimensions of these cells are plastic: should the aggressive fish meet a larger and/or more aggressive fish, the hypothalamic neurons of the defeated male will rapidly shrink. After the hypothalamic cells have shrunk, the male's testes follow suit, decreasing the fish's apparent desire and ability to breed. In the laboratory, some male fish were *environmentally pushed* from dominators to meek types; some from meek types to dominators. Their *cellular changes followed*. When a dominator emerged socially, he began to flaunt his success: physical changes began; he grew bigger and his coat brighter; his gonads swelled, and started making sperm.

Dr. Fernald found that key behavioral changes occurred first, and drove the brain changes. The dramatic growth in brain cells that produce gonadotropic-releasing hormone followed environmental change; and testicular and color changes followed that brain cell change.

Social change alters brain cells.

That is not a great surprise, but it is a relatively tidy research demonstration of what many of us who think biopsychosocially assume is routine interaction of brain and mind. We usually do not, however, have tools with which to measure such changes in vivo in humans. In fact, you might note that given our access to somewhat different aspects of fish than of humans, the *psychological middle ground* is not prominent or explicit in this fish research. (How does the fish feel or think about all this?) The demonstrations relied largely on the anatomical/physiological and the social, with the psychological middle level of description merely implicit.

With better (and less intrusive or harmful) tools (as, for example, some of our new neuroimaging techniques), we already are to some extent, and soon will be to a greater extent, able to demonstrate many similar bits of biosocial and biopsychosocial continuity in humans.

Enough about fish. I would, after all, like you to notice not just biopsychosocial integration but also humane values.

Good clinicians live by humane values and biopsychosocial integration.

Humane values require us, in promoting mental health and fighting mental illness, to be aware of and care for and treat *whole people in context* and *over time*: whole biopsychosocial people in context and over time. Some of you may realize that this requirement is right but also a bit nostalgic, and sometimes impossible. So it is. Many goals and standards are. Some of you may also realize that child psychiatry is traditionally closer to this ideal than adult psychiatry is—and that may create some useful tension in your minds, because child psychiatry has also traditionally been *less* good at acquiring a base of crisp, quantifiable research studies.

Humane values require doing, teaching, researching, preventing, and, in the real world, getting involved in some political and economic and public affairs areas on behalf of mental health. Humane values require us to fight stigma (and APA may have helped make some

gains here in recent years). Humane values should also lead us to special interest in the underdog, and those who are different. In my case, this has involved international affairs and ethics and human rights and child psychiatry. But in all our cases, it should involve interest in the old and the young, in cross-cultural psychiatry, American Indian issues, black issues, Hispanic issues, Asian-American issues, gay issues, and women's issues. To be humane to ourselves, we all have to select some areas of special interest, but we can retain an active view of the whole field around our expertise.

We each know that we cannot know all of psychiatry, and that increases in the field's knowledge can seem in a general theoretical way welcome, but in a personal way, burdensome. It is hard to keep up. We may even resent some of our colleagues who do keep up, at least in some areas; and probably many of us are tempted to resent or even reject colleagues who know and do different things.

Reasons for splits and reductionism are many, but in addition to economic pressures, and unbalancing advances in measurable and published research in one or two sectors of our field, we may be tempted into reductionism by unacknowledged frustration in a field that seems too big to master, and too bedeviled by outsiders who push us, and sometimes pay us, to simplify. Even if we know with our heads that integration plus cross-fertilization of new with traditional areas of psychiatry is right, many of us are now guilty of biological reductionism, just as some of us are, and more of us recently were, guilty of environmental or psychodynamic reductionism.

Some psychiatrists, and patients and others, now think of psychoanalysis as irrelevant and passé. Some psychoanalysts and psychotherapists, and patients, now think of psychiatry as hopelessly biologically reductionist. Some psychiatric residencies now hardly take psychodynamic psychiatry seriously.

I used to think that psychiatrists characterologically tolerated and liked and respected complexity—as opposed for instance to some surgeons, who often seem to me to want to cut decisively through all tissues and issues. But in a time of scientific complexity and economic frustrations, I have met a good many psychiatrists who seem to yearn for simplicity.

I make a distinction between clarifying, which is usually a virtue, and simplifying, which is often not a virtue.

There is also a tendency in complex fields, or eras, to split off parts (and sometimes to master them, or at least label them). Subspecialization in psychiatry is here, and has many advantages. But good subspecialization should retain awareness of the whole field. Creating subspecialty expertise is fine, but implying that there is reality, as opposed to marketing usefulness, in spinning off a new so-called "clinic" for each of one or two or three dozen *DSM-III* diagnoses, is going a bit far (and reminds me of the early twentieth-century habit of labeling hundreds of separate phobias, each neatly in Latin or Greek. I particularly liked *triskaidekaphobia*).

Splitting is here. Splits are here. Some famous splits

in psychiatry have depended on personalities in conflict, but many have developed in response to different access to different data, or different understanding of different data.

New data are abundant in our complex and lively field, but there is relatively little agreed upon integration of the biopsychosocial data. That contributes to a split between researchers and clinicians; between or among more biological, more psychological, and more social psychiatrists; and between those most interested in severe and chronic mental illness (e.g., psychoses) and those most interested in the larger number of people with mild to moderate mental illness (e.g., character disorders and neuroses). The last split, like some others in American psychiatry over the past 25 years, has probably grown, and not just as a reasonable or proportionate response to previous overenthusiasms or to good new knowledge.

There are currently major pressures on us to widen the split between severe mental disorders and mild to moderate mental disorders. Money pushes the split wider in several ways, including pressures from insurance and managed care and others to see only what is physical as real, to reduce psychiatry to acute care, to medicate symptoms rather than treat patients; and also including large pharmaceutical company support for some kinds of psychiatric understanding and treatment, but far less, if any, for other kinds.

In several courts and state legislatures, and in several insurance plans and regulations, there have been efforts to ensure that if and only if a mental illness has a demonstrable organic component should its treatment be covered well, or at all, by insurance. That is an interesting splitting dilemma for psychiatry.

In a climate of routine discrimination against coverage of mental illness, the California Psychiatric Society, for instance, has chosen to try to get better insurance for the most severe mental illnesses by asking that those, but not other mental illnesses, be covered parallel to physical illnesses.

The Alliance for the Mentally Ill, a large and effective group mostly of relatives of severely mentally ill people, very much favors this approach, and wants to fund and develop the biological end of the biopsychosocial spectrum, while caring little about, and often disparaging, psychodynamics, psychotherapy, and the psychosocial areas of mental illness.

Similarly, far from California, a New England legislator, much influenced by the Alliance for the Mentally Ill, has just taken a similar tack, with considerable skill and success in Maine. She argues that getting good coverage for what she defines as more or less "real," that is, "physical" mental illnesses, is good in itself; and could be a way of getting the camel's nose of psychiatric diagnoses into the tent of nondiscriminatory coverage. I am afraid it is far likelier to let a few in and keep most out, and even to increase splitting and infighting among the mentally ill and their advocates and helpers. Rather than a part of one camel with one body, the mentally ill are millions of separate, relatively weak people, rela-

tively easy, on multiple grounds, to separate and keep out. It is somewhat analogous to a bunch of sophomores getting into a club and keeping fiercely out a lot of other sophomores, and the larger group of freshmen or freshmen women.

Tactics get argued about, but I think we need to work for good insurance coverage of *all* mental illness, as much as possible on a par with coverage of physical illness. I expect that *all* mental illness has physical correlates in the brain, even if so far we are only beginning to be able to demonstrate a tiny edge of these, and even if demonstrating brain correlates does not validly demonstrate severe or meaningful illness.

Problems with boundaries of insurance coverage have significantly affected definitions and concepts and boundaries in psychiatry. Psychiatry that is interested only in psychosis, and in the most severely ill, seems to me a bad retreat to the late nineteenth century. Despite its tactical helpfulness to some patients in the short run, it is, I think, strategically unwise in the long run.

We have learned in this century a great deal about psychology, psychodynamics, development, family therapy, social psychiatry. Also a great deal about prevention, a politically difficult and vastly neglected field. We are currently losing some of that, and we should fight to reverse these losses. Those areas do not contradict biological, physiological psychiatry. The areas in most ways complement one another.

We need continued integration of biopsychosocial knowledge. Who is going to do that? Can we expect our trainees to do it if some of us do not do it well ourselves?

The whole area of bio versus psycho versus social will probably remain central to psychiatry for a while, and an area where we are at risk of major premature closures. One could call the risk intellectual and clinical segregation rather than integration.

Can we cooperate? It is easy to denigrate those who think differently, or who know different things. Psychiatrists do this to psychologists, but also to psychiatrists, to neurologists, to internists, and to many others. Some simplification, for a while, for a purpose, is often essential and productive, e.g., for some clear research. But in a complex field, with many simultaneously active variables, and different levels of research and clinical access, continual back and forth motion between analysis and synthesis seems to me essential. So does some *extra* effort to study what is *hard* to study and *long* to study, not just what is relatively easy and fast to quantify and publish. Cooperation and tolerance of complexity seem to me hard but essential in a complex field like brain plus mind plus influences on brain and mind that result in health and illness.

Clinicians accept imperfect complex approaches and approximations, educated guesses and re-guesses and syntheses and summaries, often nowadays informed by considerable education not just in psychodynamics but in medicine, genetics, brain physiology, psychopharmacology, developmental psychology, family dynamics, and some sociology and anthropology.

That is clinical psychiatric integration.

Many researchers, as opposed to clinicians, are impatient with much of this, and for their good reasons want to isolate factors and measure crisp, measurable units. They have made and will make some brilliant advances. But psychiatry remains at some risk as a science, and as an insurable medical specialty, partly because its complexity makes it a major example of a general problem in science: what is easiest to measure tends to get measured and called real, or important; what is harder to measure, even if as important, or more important, gets dismissed from reality, and gets measured and valued far less.

At a health-care economics symposium this year, someone claimed that by saying this, I am against measurement. Not at all. That is a mischievous and perhaps defensive mis-hearing. What is easier to measure gets measured far more, and that is a complex danger for psychiatry.

Good long-term studies are few. Good integrative studies are few. Good studies of psychodynamics and psychotherapy are very few, and those few tend to be narrow and short-term.

It has been calculated that to do good controlled studies of psychotherapy of the major *DSM-III-R* axis I diagnoses would take decades, and billions of dollars. That does not mean such studies are not important. But, badly as we need some such studies, it does mean they probably will not be done. And that leaves us relatively vulnerable, and open to being run by nonclinical simplifiers.

DSM-III and *DSM-III-R* and *DSM-IV* inevitably come into this discussion, as they are useful to nonclinical simplifiers. Part of the movement toward reliable categorization and measurement, they have helped many aspects of psychiatry, but harmed many others. They emphasize clarity and reliability, but sacrifice validity and the whole person. There are vigorous signs of diagnostic life outside of *DSM-III-R* axis I—e.g., complex interest in axis II; in axes III, IV, and V; in possible added axes; in etiology; in comorbidity and dual diagnoses (which are now ubiquitous and slippery); in reactive disorders; in psychodynamics; in development and adaptation as part of diagnosis, especially in youngsters; in family and social stressors; in protective factors.

All these persist outside *DSM-III-R* and *DSM-IV*. Life is complex. Clinicians integrate what we can.

Perhaps in some ways similarly, at different levels, organizations like APA integrate what we can, even if there are always hundreds of simultaneous issues to work out. As last year in this setting, I can barely begin to list, much less discuss, all that APA does in a year. For a good summary, including good notes on APA activity with the resource-based relative value scale and Medicare, I refer you to recent APA staff summaries, and to the annual Medical Director's report. But before ending with a few words about children, I would like briefly to touch three topics that members around the country have talked to me about repeatedly: managed care and universal access; psychologists; and ethics.

Managed care, variously defined, is a huge concern, very much here, and popular with many in government and business. It is not at all popular with many—probably most—psychiatrists. I think many psychiatrists hate it, and feel terribly worn down and wasted by it. And as to patients and the public, they are mostly still not yet sufficiently aware of or educated about it. Quite aside from its many conspicuous abuses, such as wearing down clinicians by harassment and paperwork, it is driven by a large interest in *cost cutting* (not quality enhancement) as the ruling concern; of *shifting power* away from doctor, and patient, to third and fourth parties without medical degrees; and of *overruling what is best for an individual* patient with what someone thinks is good for a larger entity (at best, society, but very often just a managed care or insurance company's short-term profits). These driving interests are often disguised.

Managed care has private and public arms. It is part of the current inherently flawed push to "privatize" public psychiatric programs, and is nearly certain to be, in some form, part of any universal access to health care plan for the United States. Universal access is long overdue in America, where tens of millions of us are currently left out of our health nonsystem. Access should include *as much as possible* mental illness care coverage, *as equal as possible* to physical illness care coverage. Canada and Germany are highly useful models, despite propaganda to the contrary. It is not just mental illness but all health care that is not well covered in the United States. And capitalism, to the surprise of some Americans, survives in the vast majority of industrialized nations, all of which have universal access to health care. This year there are being discussed in Congress a dozen or so major universal-access-to-health-care plans, proposed by major organizations and by some members of Congress. One gathers that not one of these is likely to pass this year, but we are getting closer.

Universal access is overdue, but managed care (even the rare best of managed care, run with legitimate physician peer review) is not "the answer" to high health care costs. It can contribute at best a moderate part of an approach to high health care costs, though its aggressive use of businesslike vocabulary often implies or claims much more.

I do not think our health care costs are too high in America. We spend about as much on alcohol and tobacco, for instance, as we do on health care. In fact, I think we probably spend too little on health care. (What an eccentric I am!) I think that guns and butter should be a major issue to anyone interested in health and mental health, and I think America vastly overspends on military matters, and underspends on investing in people and health. But to persuade the American public, the American government, and the American business establishment to change values, and spend less on the military and more on health, will require major work.

Then psychologists. Are boundaries possible? We go on being uneasy allies, with some big disagreements that get in the way of potential cooperative work. Are

the noisiest disagreements really turf wars, or are they legitimate safety and quality-of-care-of-patient issues? Can we as professionals insist on any standards, or are all *standards* thought to be undemocratic, or greedy, or violations of antitrust laws? Nearly all psychiatrists I have heard from, and a gratifying number of psychologists, agree with my last year's Boston-influenced slogan: No medication without medical education.

Then ethics: Despite America's widespread assumption that ethics means sex, ethics does not at all mean just sex. It means good and decent behavior, good professional behavior, good care. Ethical questions around money, for instance, and responsible inpatient and outpatient practice decisions, certainly including managed care, are currently lively. But for posterity's sake, I would like to record that perhaps never in the history of the American Psychiatric Association has an APA president been called upon to spend so much of his time considering psychiatrist-patient sexual contact as this year. There has been much publicity about several cases, much of it feelingful and inaccurate—as news coverage of sensational topics often is. That the great majority of psychiatrists behave well and safely, and work hard never to harm their patients, does not quite protect us. APA and the public are rightly concerned about the issue, and clear as many of us think our ethics code and procedures are, we clearly need to do better. That will include prevention and education; openness; clear and firm standards; and due process, including punishments, to uphold standards. We have much of this in place now (far more than the media usually acknowledge, and far more than the public and many of our own members know, and more than any other national professional organization that I am aware of). Yet we need to do more, greatly to reduce bad behavior and to demonstrate that part of profession is to have and insist on clear, high, ethical standards.

Let me end, as I often do, with a few words about children. I regularly introduce children into my remarks on humane values and biopsychosocial integration because I like to work with, and teach about, children and adolescents as well as adults; but also because it seems so clear to me that child psychiatric pathology and health, including severe pathology, and even in the minority of cases, where there are demonstrable organic problems—child psychiatric pathology and health are very dependent on family and environment, i.e., on the social end of "biopsychosocial" that is so often left out of 1992 psychiatric discourse.

I recommend to you David Hamburg's new book, *Today's Children: Creating a Future for a Generation in Crisis* (5). Among the advanced countries of Western Europe and Japan, Hamburg says, "the United States now ranks in the bottom quartile in caring for children." He says that the United States is committing "atrocities," and that we have already lost a substantial portion of the generation of children under age 16. His book is full of sad facts, but also of psychiatrically educated suggestions, especially for prebirth and infancy, and the junior high school years.

Do we as a society particularly dislike children? Probably not. But we pretend to like them more than we do. And, as I frequently point out, children don't vote. They are poor. They lack some mature political skills. They depend on others. And they are rarely desperately and immediately scary to adults. Short-term thinking—which most politicians are best at—allows us to ignore and shortchange children and adolescents, and thus our own field and our own future.

All the statistics that I cited last year on abuse and neglect and foster care, and homeless and at-risk and psychiatrically disordered children, remain similar or worse.

Twenty percent of United States youngsters live below the poverty line. In cities, 30%. Among Hispanics, 39%. Among blacks, 45%.

The numbers of children in our very flawed and unsafe system of foster care is still about 350,000, and the number of homeless youngsters is still around 200,000; 7.5 million children still need treatment for diagnosable mental disorders.

Unwed teenage pregnancies still are an epidemic in the United States: every year, about one million unwed teenage girls, about one in ten every year, become pregnant. The rates of births to unwed teenagers, most destined for poverty and major additional problems, have about quadrupled in the past 25 years. Not just abortion information, but even more basic and less controversial *prevention* education—to prevent both pregnancy and AIDS—is severely and shamefully hampered and blocked in the United States. Teenage drug and alcohol use rates are still huge (even if cocaine may have peaked), and every year 2.5 million teenagers contract a sexually transmitted disease—which by now implies not just visible disease, but a very large pool of so far undetected HIV-positive teenagers.

And violence? Rape and murder rates are staggering. Teenage violence is taken for granted in America today, but it increasingly involves guns and death (and the United States has a limp lack of social policy to deal with this). The average American 16-year-old has seen 100,000 acts of violence on television. On the average day, 135,000 youngsters bring guns to school.

There are, I recently learned, 200 million guns scattered about the United States; and gun merchants worry that the market is slowing down. And, a quieter little statistic, how many people are licensed to sell guns in

the United States? 270,000. Guns are cheap and technically terrific. A 13-year-old holding an Uzi submachine gun has little understanding of his own mortality, let alone your mortality or mine—but as a slum teenager who had shot at and, he thought, hit people, said, “they were just people.” “It’s like an article of clothing . . . I put on my pants, my shirt, my hat, and my gun.”

Social policy and family policy are intricately tied to child and adolescent health and mental health. Social policies do not rest on perfect proofs, but on wisdom and experience. We have much wisdom and experience as to child rearing and preventing problems and fostering strengths in young people, and we are ignoring much of our own wisdom and experience, and not fighting for it. Psychiatry can and should contribute to reasonable, decent, educated social policy.

As I look back on a good year of hard work, and since I will at the end of this week shed the exciting honor and somewhat charmed life of an APA president, I feel a bit like Prospero at the end of *The Tempest*; not yet old, but giving up his wand and magic powers, and returning to a different reality:

Now my charms are all o'erthrown
And what strength I have's my own.

I urge you all, whatever your roles, whatever you do, whatever your particular skills and interests, whether you are clinicians, researchers, teachers, students, administrators, whatever—all of you—I urge you to invent ways of applying your talents and energies in some ways that will help biopsychosocial integration, that will help humane values, and that will help children and adolescents grow mentally healthier than they now are in America. Thank you for listening.

Response to the Presidential Address: Patient Care for the Twenty-First Century

Joseph T. English, M.D.

Dr. Hartmann and I have enjoyed an extraordinary relationship over the last year. We hardly knew each other before it became my task to assist the efforts of his presidency. I think we have agreed on nearly everything, which is quite remarkable when you consider that we are both quite opinionated. The only lapse was when he once suggested, while addressing a meeting, that the Irish could be wrong about something. I don't think he realized, at the time, that English is Irish. But we have been able to straighten out even this problem. I was quite sure of it when he wore an emerald green tie to the reception that evening.

In some way, I think this incident captures the essence of Lawrence Hartmann's presidency and the powerful impact it has had. We are a most diverse profession, and that diversity is our strength. Dr. Hartmann's theme, celebrating the humane values that bind us together as a profession as well as the balance and tolerance we achieve through the concept of biopsychosocial integration, is precisely the message we need to hear in these turbulent times. As the most tolerant of the medical specialists, we must be understanding of each other and in our practice. In this he has provided superb leadership and example.

As an illustration of this, Dr. Hartmann was able to bring together the elected leadership of APA and of the American Psychological Association for an unprecedented full day meeting. There is a rumor that the Secretary of State tried to reach him for advice after that feat. Just this week, the two APAs met with the leadership of the American Nursing Association and the National Association of Social Workers. Under Larry's leadership, it was clear where we disagreed, but it was made increasingly clear where we could collaborate for the sake of our patients and in the public interest. And he did this as he has done so many other things for us, with warmth and wit, with scholarship and sophistication. His distinguished parents would be proud. And we are grateful.

But I now remind myself that, above all else, the

President-Elect should be brief. I cannot afford to have my judgment questioned at the inception of my term.

Let me tell you of my hopes and aspirations for the year to come.

My choice of theme complements Dr. Hartmann's. I chose it after consulting with hundreds of colleagues, some of whom wrote to me eloquently, and many of whom are in this audience tonight. For this help, I am grateful.

My theme for the next year will be Patient Care for the Twenty-First Century: Asserting Professional Values Amidst Economic Constraints.

As the twentieth century draws to a close, we find ourselves in the midst of the most important health policy debate since the decade of the 1960s, which gave birth to Medicare and Medicaid and the beginnings of public insurance for all in need of medical care in the United States. This was a generous period in our nation's history, when we dared to think that access to health care was an entitlement, derived from the right to life itself.

We now find ourselves in a different time, when the question more often involves the triage of human life. The physician is asked to decide who shall receive care and who shall not. Soon it may be a question of who shall live and who shall die. After all, society has other needs and health care has become a favorite target for cutting costs. In these times we are told that we need "managed care." How ironic. Psychiatrists have joined together to manage the care of patients in the United States for 148 years; it was that long ago that we became the first of the medical specialties in the United States to organize a medical association to advance this important work. We will soon celebrate our 150th anniversary in Philadelphia, where our founder, Benjamin Rush, was organizing care for patients with mental illness even before we had become an independent nation.

What we are really being told is that others want to manage the care of our patients, but not necessarily in the tradition of Hippocrates. There are stockholders to be considered, the competitiveness of American business, the federal deficit, and public and private budgets to be balanced. In the process, we find that many of our patients are excluded, and that even more are being placed at risk.

Jay Cutler will tell you that there is no health reform initiative under consideration by Congress in which our patients and our practice are not at risk. In many of

Presented at the 145th annual meeting of the American Psychiatric Association, Washington, D.C., May 2-7, 1992. Dr. English, 121st President of the American Psychiatric Association, is Chairman of Psychiatry, St. Vincent's Hospital and Medical Center, and Professor of Psychiatry and Associate Dean, New York Medical College. Address reprint requests to Dr. English, St. Vincent's Hospital and Medical Center, 203 West 12th St., New York, NY 10011.

them, mental illness is not mentioned at all. With our powerful and effective government relations organization, we react to such challenges brilliantly, and often successfully. But these times require more and demand the efforts of all of us.

At the midpoint of this century, a group of psychiatrists came back from extraordinary service in World War II and saw a time of opportunity. Their names are legend: Braceland, Ewalt, Menninger, Felix, Grinker, Sullivan, Appel, Tarjan, to mention a few.

They convinced President Eisenhower and the Congress of the United States to embark upon a great study of the mental health needs of our people. They hoped that World War II would be the last war and that we could apply the lessons they had learned to radical improvement of mental health services here at home. Their leadership brought about the Joint Commission on Mental Illness and Health. This commission included all of the mental health professions together with citizen organizations—and the American Psychiatric Association played a crucial leadership role.

The product of their work was given to a new, young President, John Kennedy, who in 1963, shortly before we lost him, sent the first message to Congress on mental health and mental retardation, outlining a plan of legislative action to benefit the mentally ill and the mentally retarded. This work laid the template for mental health services for the remainder of this century.

But it also left much to be done.

It is time for us to begin a similar effort to ensure the well-being of our patients in the twenty-first century, with the same commitment and dedication and with a much greater chance for a century of peace in the world than our predecessors could ever have envisioned.

To begin, I plan to ask the Board and Assembly for their authorization to initiate a process of strategic planning for APA and to engage the talent we need to assist us. Such a process will go beyond reacting to the crises of the moment. It will help us to set goals and priorities to debate the crucial options, to develop action plans for implementation, with accountability to the membership should we fall short. I have chosen three major areas for the initial engagement of this process.

The first is health policy. Our goal will be to ensure that the needs of our patients are met. But we must define those needs clearly and precisely and develop short- and long-term objectives to address them. We will have to make some tough choices, because in these times you can't have it all. Bob Gibson, who did so much to guide our economic initiatives in the 1960s, has accepted reappointment as leader of the Council on Economic Affairs and has accepted a major responsibility in the development of this strategic plan, together with John McGrath, who has agreed to continue as chair of the Joint Commission on Government Relations, with Steve Sharfstein and Don Scherl, with Jay Cutler and his staff, and with the leadership of the Board and Assembly. The planning for this effort is already underway; the first meeting is scheduled for July 1992.

Richard Surles, Mental Health Commissioner of the State of New York, has agreed to help us reestablish our historic community of interest with the states and to develop the new definition of public/private partnerships that the new century will require. The National Institute of Mental Health has already offered us its resources and participation. The Hastings Institute, with a similar effort already underway, has agreed enthusiastically to collaborate with us. And, as we develop our plan, we shall reach out to the other mental health professions, to our colleagues in organized medicine, and especially to patient and citizen organizations.

All of this is being coordinated by the master strategist who is our Medical Director, Mel Sabshin. How fortunate we are to have his wisdom and experience to guide this important effort.

Our developing product will be shared with the membership at every opportunity, but especially during our Institute on Hospital and Community Psychiatry in Toronto and our next annual meeting in San Francisco.

The process will be participatory, and its spirit should be that of a little-known Peace Corpsman from Pennsylvania, who took the issue of health care to the people of his state, winning election to the U.S. Senate despite incredible odds and making his state and the nation awaken to the political importance of health care as an entitlement. And when Harris Wofford heard in his suite that he had done it, your President-Elect was there and was the first physician in this country to offer him congratulations on your behalf. We have friends, and we must help them with our planning, and they will help us.

The second area is the recruitment of young talent to our profession. There is no need to plan for the future if we do not attract the young to join our ranks in the present. Here we have our work cut out for us. The 30% decline in medical students entering psychiatry's match this year should galvanize us to action.

The appointment of a director for APA's Office of Medical Education shall have my highest priority. In addition, I intend to meet with the academic chairmen of our field, a powerful and talented group, to urge them to place an even greater emphasis on undergraduate medical education and on efforts to attract talented medical students to psychiatry. Our reach must extend into the liberal arts colleges and into the high schools of our communities as well.

We have succeeded in celebrating our science, but there are other aspects of psychiatry's mission that will also appeal to the young, and we must rediscover this message and work energetically to deliver it.

I am delighted to report that James Shore of Colorado has accepted the leadership of APA's Council on Medical Education and Career Development and will lead the effort to develop our strategic plan in this area. No one in APA is better equipped to provide us with leadership in this crucial area.

The third area for action is the public perception of psychiatry. When the film that wins all the major Academy awards is about a psychiatrist who eats his pa-

tients, we have a problem. When in many other films, psychiatrists are having sex with patients; when all of this is not just going on in the movies; when such abuse is the subject of a cover story in *Newsweek* and lead stories in major newspapers, magazines, and public television documentaries (two on network television in a period of 10 days); when we are called bounty hunters and kidnappers of patients in Congressional hearings, we truly have our work cut out for us.

We know that we are much better than that. It is a small fringe of our profession who are involved in such abuse. We should be proud that no specialty of medicine has worked harder to enforce the code of medical ethics. We know that we have incurred enormous expense to remove or suspend for ethical abuse more than 100 members of APA over the last 10 years, always with careful attention to due process and good procedure, but we must also ensure that the public knows it and appreciates our continuing commitment.

I am delighted to report to you that Edward Hanin has agreed to chair APA's Joint Commission on Public Affairs and is already hard at work on the development of a strategic plan for new initiatives in this area. Also, I am grateful to the Board for approving a waiver so that the splendid leadership of our Ethics Committee may be continued by Jeremy Lazarus over the next year. Having spent two days with this committee under Jeremy's leadership during its recent meeting, I can personally attest to the quality of their work and the service they render our profession. But we must ensure that knowledge of our ethical code by the membership and the teaching of it to our medical students and residents receive a new priority and emphasis. Dr. Lazarus will give us superb leadership in this endeavor.

Clearly, all of this is interrelated. We shall succeed in the political process if we retain the confidence and support of the public. To maintain this confidence, we must demonstrate a renewed and highly visible commitment to professional and ethical values. Nothing could help more to maintain and enhance the public perception of psychiatry. And such efforts will help us to attract medical students to our field.

Because of what has been happening in many of the cities we left to come to this meeting, may I leave you with a few additional thoughts.

More than 200 years ago, Benjamin Rush was asked to lead a small planning group to develop some working papers, which were then given to Thomas Jefferson. Jefferson used those papers in writing the Declaration of Independence. The power of those ideas has demolished the Berlin Wall, torn asunder the Iron Curtain, and brought freedom to the people of Eastern Europe. Those ideas now make possible the free practice of medicine and the demise of the abuse of psychiatry by the power of the state. But we need to remind ourselves that the promise of these ideas is yet unfulfilled for many here in our own country.

Twenty-five years ago, in the wake of the riots that

followed the death of Martin Luther King, President Lyndon Johnson appointed the Kerner Commission to make recommendations that would avoid another such a national tragedy. He asked a psychiatrist, Walter Menninger, to serve on that commission. And we should recall this evening what the Kerner Commission said then, and I quote, "Our nation is moving towards two societies, one black, one white, separate and unequal." The tragic events of the last few days make these words crash back into our consciousness as never before. But even more importantly, we should remember that a war on poverty was declared and that programs like Head Start, Neighborhood Health Centers, Foster Grandparents, the Job Corps, and Vista began to flourish all over the land. And psychiatrists helped with all of these efforts. We also had the Peace Corps, ably led by Sargent Shriver, the commanding general of the war against poverty. But sadly, another war retarded the efforts of the war on poverty, leaving much yet to be done. On this first Sunday in May, which national leaders have asked to be a day of reconciliation, let us enter into that spirit and join with those who say that it is time to make a new beginning.

As APA initiates its planning process for the twenty-first century, let us work and plan for public mental health in the largest sense. Public mental health should involve more than reimbursement and economics; it should include how we do our part to help end the plague of racism and alienation in this country through a new understanding of what "one nation, indivisible" is all about.

Our patients come first, but they need more than treatment. We must be interested in catchment areas, but our concern should be that they become caring communities. We should never return to the days when our reach exceeded our grasp, but that does not mean that we should fear to reach out with our professional skills and commitment when our help is needed.

I spoke to Gary Tischler, Chairman of the Department of Psychiatry at the University of California in Los Angeles, at a symposium honoring Danny Freedman. Dr. Tischler told me that his department has already been asked by the public school system in Los Angeles to participate in efforts that would help schoolchildren understand what has just happened in their city. The faculty of his department drew straws to see who would come to Washington for our meeting and who would stay behind to plan this help. Let us look for such opportunities and offer assistance even before we are asked.

When we gather in San Francisco next May for our annual meeting and review our strategic plans for patient care in the twenty-first century, let us also be prepared to tell each other tales of how we labored during the year to promote understanding of what "one nation, indivisible" is really all about.

I look forward to working with you in the year before us. Thank you.

Lawrence Hartmann, M.D., One Hundred Twentieth President, 1991–1992

Melvin Sabshin, M.D.

Our 120th President, Lawrence Hartmann, is an extraordinarily *cultured* man. His theme, Humane Values and Biopsychosocial Integration, is profoundly autobiographical as well as a credo for the *next* phase of psychiatry and a celebration of what good clinicians do now.

A product of distinguished Austrian families, Larry has had a life history and professional career (or perhaps careers) that are a remarkable integration of diverse forces, paradoxes, multiculturalism, talents, styles, and personal philosophy. It is a special privilege for me to introduce our President. While I have known him for almost two decades, a series of professional and personal events have drawn us much closer during his presidential year. I will always remember the personal warmth and support that emanated from Larry, belying, but also complementing, his austere and *occasionally* royal surface demeanor.

The life stories of past presidents of APA have often been fascinating tales of how outstanding women and men chose or discovered a pathway into psychiatry and rose to leadership positions. Rarely, however, have we had a President whose personal life has intertwined so closely with the history of psychiatry in Europe and the United States and, indeed, the whole world. World War II, its antecedents and its aftermath, changed psychiatry radically. Indeed, in the United States the face of psychiatry altered fundamentally after the war, and the consequences of those dramatic events continue to influence our complex mosaic of values and practices. Lawrence Hartmann's roots, his family, and his own career up through his presidency of APA mirror these developments and also shaped them.

Larry's father, Heinz Hartmann, was, of course, one of the most significant theoreticians in the entire history of psychoanalysis. His work on ego psychology was seminal in several senses. It brought forth a promising new phase of world psychiatry as well as psychoanalysis. It opened a pathway for research on ego psychology and adaptation that still remains to be plumbed from a biopsychosocial and/or a psychobiological perspective. Heinz Hartmann's move to the United States reflected the postwar emigration of Austro-German intellectuals

to this country. America became the world's center for psychoanalysis, and the impact of this development on America's psychiatry was momentous. Indeed, for a quarter of a century, American psychiatry was dominated by analytic theory and practice. Dora Hartmann, Larry's mother, was also a most distinguished psychoanalyst. Her prior career in pediatrics, before immersion into analysis, presaged Larry's capacities and motivation for child psychiatry, as did her love of games and sports, including mountaineering.

On both sides of his family, our President inherited and applied proclivities and capacities for a vigorous intellectual, artistic, athletic, and public life. A paternal great-grandfather was a leader in the Austrian revolution of 1848; he combined talents in poetry and prose with his political work. (Wouldn't it be nice if countries other than Czechoslovakia and the Ivory Coast facilitated leadership of this quality?) Replete with artists, physicians, historians, musicians, ambassadors, educators, naturalists, and many free spirits, Larry's family was cosmopolitan in the best sense of the word. It would be reductionistic, however, to formulate our President's life and career in simplistic continuity terms. Discontinuities, personal bents, and preferences have played a significant role. While influenced deeply by psychoanalysis—including a personal analysis—he has chosen a pathway that blends parental and family history into his own amalgam of interests in work and love. His companion, Brian Pfeiffer, with whom he has shared affection, intellectual interests, and travel for two decades, has also had a distinguished career in architectural history. Brian's special interest in philosophy, social criticism, and his energetic love of life complement Larry's style and scope. Ernest Hartmann, Larry's brother, demonstrates his own pattern of family continuity. Ernest is also a psychiatrist, and he is a psychoanalyst like his parents. He, too, however, has carved out his own career niche. Ernest Hartmann's commitments to research in the biology of sleep and dreaming have been creative and productive. More recently, Ernest's work on boundaries in the mind is redolent of Heinz Hartmann's contributions 50 years ago, but it is also different in method and concept. The brothers, Ernest and Larry, have different individual styles; Larry's interests are more clinical and educational, although he has mused occasionally in the past about converting his respect for new ideas and research into more of an investigative and theoretical career.

John Kennedy once had fun saying, at a Yale com-

Presented at the 145th annual meeting of the American Psychiatric Association, Washington, D.C., May 2–7, 1992. Dr. Sabshin is Medical Director of APA. Address reprint requests to Dr. Sabshin, APA, 1400 K St., N.W., Washington, DC 20005.

mencement where he was an honoree, that he now had the best of two possible worlds, a Harvard education and a Yale degree. Larry Hartmann has had the best of several worlds. His family moved from Vienna when he was one year old. They lived in Paris for a year, and Larry's first language was French, which he used and implemented in Geneva and Lausanne, prior to his move to New York when he was almost four. To be Larry Hartmann and to have grown up in Manhattan in the 1940s and early 1950s was a marvelous opportunity. The schools were first-rate, stimulating, and thorough. How nice to be a teacher and have a student who thrived in mathematics, English, sports, and the pleasure of learning.

Even before he matriculated at Harvard College, Larry's talents in literature, opera, and drama began to blossom. His love of classics has remained central to his life, up to the present. Recently, on a trip to Leningrad, Russian colleagues were surprised and very pleased to work with an American colleague so well steeped in their literary tradition. Once again, however, even in these passions there was discontinuity as well as continuity. Larry created his own mixture of classicism, personal history, and dry wit. At age 17 he wrote a spoof of Hamlet in which the prince was converted into the son of a Park Avenue psychoanalyst. Naturally, he starred in this drama. I wish I had seen it! At Harvard College, Larry immersed himself in history as well as literature. He served on the editorial board of the *Harvard Crimson* and was a drama critic, obviously preparing himself for a role in APA. In retrospect, it is not surprising that Larry was selected to be a Rhodes Scholar at Oxford, for work in English literature. What a marvelous opportunity to seep himself in college life, to walk, to make friends, and to be so close to the London drama scene. His admiration for Olivier, Gielgud, Richardson, and others was able to mature, and he continues that special interest today.

Fortunately for us, given the panoply of career choices, Larry opted to attend Harvard Medical School. He interned in pediatrics at the University of California at San Francisco and returned to Boston for psychiatric residency at the Massachusetts Mental Health Center. At that time, in the mid 1960s, the Center was a mecca for many gifted trainees. Its tradition was to produce first-rate educators, clinicians, and researchers with a commitment to public service. Humane Values and Biopsychosocial Integration could have been its credo also, but its special role in creating the dominant psychiatric ideological tenets of the 1960s was apparent to many; perhaps early in the next century another retrospective look at those values will help us reflect. The *Zeitgeist* of the Center, like the *Zeitgeist* of Manhattan at an earlier phase of Larry's life, influenced his adult development in a number of special ways. Commitment to social issues, broadly and specifically, and their place in psychiatry was very strong in teachers and leaders at the Center, and many students also became determined to change the shape of American psychiatry. Larry identified with these values but, as always, added his own

scope to them. Particular motivations affected his creation of a professional identity that included his electing a child fellowship at the Center; child psychiatry flourished at that time also, and its attraction was clearly overdetermined. That Larry chose to work in child psychiatry (albeit not exclusively) and then move toward a career pattern that emphasized private practice and teaching was a major personal choice given the broad array of career possibilities for him. He has had the knack of finding his own clear solutions amid much complexity and diversity, and he enjoys that process very much.

Fortunately for APA, Larry Hartmann also elected to become an active participant in Association affairs at an early age. Again, the overdetermination is manifest. From his families' involvement in sociopolitical history, his multicultural perspective on biopsychosocial processes, his passion for democracy, his stimulating milieu at the Massachusetts Mental Health Center, his wish to be active in the seeking of justice and equality for children, for women, for homosexuals, and for minorities, and his penchant for clarity and precision in finding balanced solutions—all of these forces played a role in his pathway toward leadership. Also playing a role was his passion for psychiatry as a field and his growing skill in the organizational processes necessary to advance the field. These skills are an interesting sidebar to our President. He has been, and still is, a parliamentary and constitutional student and painstakingly involved in facilitating order and precise use of language. In a way he has become a constitution-writing English teacher in psychiatrists' clothing.

Larry's ascending into the leadership of APA followed a career ladder that is becoming more of a paradigm these days. His involvement on the steering committee of the National Committee of Concerned Psychiatrists from 1971 to 1975 helped to catalyze his values and commitments, but he also worked his way up the ranks in APA and the American Academy of Child and Adolescent Psychiatry. The ladder included leadership roles in the Massachusetts Psychiatric Society, which soon evolved into his membership in our Assembly, where he served from 1976 to 1985. Occasionally, in the Assembly, Larry's image was like a patrician schoolteacher, but the respect for his underlying values steadily grew; so did his respect for others in the Assembly who expressed opinions contrary to his, as long as they did it fairly and clearly. Members of the Assembly, through the marvelously satirical voice of former Speaker Bill Sorum, once had fun making a caricature of Larry Hartmann. Would the Assembly elect a politically liberal, middle European prince as its Speaker? Yes, they did, and Larry loved being Speaker—and being a prince. Conscious of diverse policy opinions of the Assembly, he was eminently fair, but he also played a decisive role in leading the Assembly toward decisions that supported minorities, equitable distribution of power, and biopsychosocial integration. As Speaker, Larry began his long-term role in the APA Board of Trustees, where he has served since 1980. As Area I trustee, he mirrored New England's activism and sense

of social and economic justice but consistently applied his own brand of balance, order, humor, and, *mirabile dictu*, pertinent clinical vignettes. Good at APA politics, Larry followed his Area I electability with successive victories for the positions of Vice-President and President-Elect. Anyone knowledgeable about APA elections could note his shrewd assessment of how to win an APA election. The Prince could work the precincts, amass significant supporters, speak at numerous gatherings of voters, and turn out the vote.

Here, in his Presidential Address, you can read Larry's own enunciation of what he has tried to accomplish during his presidential year and what he hopes and aspires for psychiatry. Complex social, political, and economic pressures have certainly made all of us uncomfortable and test the limits of our adaptability. The forces of reductionism abound in manifest and subtle fashions. Many of our members long for the perceived halcyon days of the 1960s, and regressive tendencies also have a broad appeal. This past year has had more than its share of APA fiscal problems, highly publicized events that attacked or threatened our ethical fabric, international discontinuities and turmoil, ratcheting down of medical benefits, and concerns about recruitment into psychiatry. These and many other issues have preoccupied our 120th President. Nevertheless, he has had the energy, the foresight, and the commitment to see the forest as well as the trees. He has presided with his usual balance, wit, and precision.

He has traveled extensively, including involvement in

our Eastern European project last month. Larry Hartmann has had international interests and commitments superseding those of all but a few of our previous presidents. He has sought justice for psychiatric patients in South Africa, Chile, Saudi Arabia, and, of course, the former Soviet Union. In this enormous task, the interplay between the specific psychiatric issues and general questions of human rights have been clear in Larry's mind, his writing, and his actions. Somewhere, amid intergalactic space and sounds, I think I can hear bemused applause from Larry's great-grandfather and other members of his family. These interests, however, have been balanced and complemented by his concentration on domestic concerns involving our patients, our members, our allies, our minorities, and all of the major problems they encounter.

He has faced our problems squarely but pointed us to new solutions embodying his biopsychosocial principle and the humane values that must accompany the principle. In addition, he has had the capacity and the strength to support colleagues who experienced travail and loss during the year. As one of those who felt Larry's quiet support, understanding, and help, I can attest that our President's theme is a personal and living credo that I have learned to appreciate. Yes, Larry Hartmann is an extraordinarily cultured man, and we at APA have benefited greatly from the confluence of diverse historical, personal, and professional forces impinging on him so that he has chosen to and was elected to lead the American Psychiatric Association.

Revising Axis V for DSM-IV: A Review of Measures of Social Functioning

Howard H. Goldman, M.D., Ph.D., Andrew E. Skodol, M.D., and Tamara R. Lave, B.A.

***Objective:** Axis V, which uses the Global Assessment of Functioning Scale in the multiaxial system of DSM-III-R, is under review for DSM-IV. This article examines what is known about axis V and selectively reviews the literature on measures of social functioning to identify potential alternatives to the Global Assessment of Functioning Scale. **Method:** About 25 studies on the use, reliability, and validity of axis V in DSM-III and DSM-III-R are reviewed. In addition, nearly 30 measures of social functioning are reviewed and analyzed as potential substitutes for the Global Assessment of Functioning Scale. The analysis focuses on the strengths and weaknesses of each measure for assessing functioning on axis V. **Results:** Axis V measures are modestly reliable and valid but not widely used. The authors identify and discuss two particular limitations of the Global Assessment of Functioning Scale: 1) the combination of measures of symptoms and measures of social functioning on a single axis and 2) the exclusion of physical impairments from the rating of functioning. **Conclusions:** None of the measures of social functioning reviewed is clearly superior to the Global Assessment of Functioning Scale for use on axis V. A modified version of the Global Assessment of Functioning Scale, separating the measures of social and occupational functioning from the measures of symptoms and psychological functioning, is proposed for field testing, along with a new set of instructions permitting the rating of limitations due to both physical and mental impairments.*

(Am J Psychiatry 1992; 149:1148-1156)

Axis V was introduced in *DSM-III* as a measure of "adaptive functioning" on a 7-point scale ranging from superior to grossly impaired. Axis V was modified

for *DSM-III-R* in an effort to increase its utility. According to *DSM-III-R*, axis V, the Global Assessment of Functioning Scale, is to be used to assess "psychological, social, and occupational functioning." It is "available for use in special clinical and research settings" (*DSM-III*). It is not a required element of patient evaluation and is regarded as a supplement to the "official" diagnoses (on axes I, II, and III). There is little evidence concerning how frequently axis V is used for planning treatment and predicting outcome (1).

As a result of the revision of axis V in *DSM-III-R*, a simple measure of adaptive functioning was replaced by a 90-point scale that combines assessments of psychological, social, and occupational functioning; it is based on the widely used Global Assessment Scale (GAS) (2). It was thought that the Global Assessment of Functioning Scale would be a more useful element of the multiaxial evaluation system than *DSM-III* axis V, because the GAS has been used in hundreds of studies and clini-

Received May 20, 1991; revision received Dec. 18, 1991; accepted Jan. 24, 1992. cal settings. There is little or no information, however, on the impact of the changes made for *DSM-III-R* on the utility or acceptability of this supplementary axis.

This report reviews what is known about axis V of *DSM-III* and *DSM-III-R*, reviews other measures of social functioning, and discusses several options for proposed further revision of axis V for *DSM-IV*.

RELIABILITY AND VALIDITY OF AXIS V

A number of published studies have addressed the reliability or validity of *DSM-III* axis V.

Reliability

In the *DSM-III* field trials, the intraclass correlation coefficient (ICC) for axis V ratings of adult patients was 0.80 when the joint interview method was used and 0.69 for test-retest evaluations (3). Fernando et al. (4) reported a lower figure of 0.49 for the ratings of a multidisciplinary group of clinical workers on an inpatient service.

Russell et al. (5) found 64% agreement between raters of cases of child psychopathology who used a preliminary version of axis V consisting of a 4-point scale of current impairment in adaptive functioning. Using *DSM-III* axis V, Mezzich et al. (6) found an ICC of 0.61 for ratings of a mixed group of child and adolescent cases. Rey et al. (7) reported an ICC of 0.57 for a group of adolescents. All three of these studies had clinicians rate written case summaries rather than the patients in person.

Overall, reliability for axis V has been found to be higher than for axis IV. Given the relatively restricted diversity of clinicians, patients, information, and time frames in the published studies, however, the demonstrated reliability of axis V has not been especially good (8). Although special training in the use of the measures of functioning for axis V may improve reliability, we are not aware of any studies of the impact of training.

Validity

Most validity studies have compared adaptive functioning as measured by axis V for different patient groups identified by diagnosis or referral status. A few have approached concurrent or construct validity by comparing axis V ratings to other measures of adaptive functioning. The relation between axis V and disposition or treatment status has been studied, mostly retrospectively. Two studies have used prospective designs to examine the predictive validity of axis V.

Five studies have reported predictable diagnostic group differences on axis V in diverse patient populations. In a mixed group of inpatients and outpatients, Skodol et al. (9) found significant variation in axis V ratings across 10 diagnostic groups; patients with schizophrenia received the poorest ratings of adaptive

functioning, and patients with V codes, no axis I diagnosis, anxiety disorders, adjustment disorder, and major depression (single episode) received the best. In a sample of more than 10,000 patients, Mezzich et al. (10) found that depressed patients had higher axis V ratings than nondepressed patients. Trzepacz et al. (11) found that liver transplantation candidates who were delirious and who were seen by a consultation-liaison service had lower axis V ratings than nondelirious patients. Westermeyer (12) reported lower levels of adaptive functioning among Asian refugees to the United States who had any axis I diagnosis than among those who had none, and Fabrega et al. (13) found a trend toward greater impairment according to axis V at intake among patients whose axis I diagnoses were more complex. These investigators found a highly significant relation between complexity of axis I disorder and deficits in *current* functioning.

A sixth study, by Schrader et al. (1), had mixed results. These authors found no difference on axis V between psychotic and nonpsychotic, psychotic and organic, or nonpsychotic and organic patient groups. When psychotic patients were divided into those with affective psychoses and those with nonaffective psychoses, the former had higher levels of functioning than the latter, who also had lower levels than patients with nonpsychotic disorders. Bronheim et al. (14) reported that patients referred for psychiatric consultation from an otolaryngology service had better functioning on axis V than other referred patients.

Three studies have examined the relation of axis V to other measures. Skodol et al. (9) compared axis V to measures of social and occupational functioning included in the Psychiatric Epidemiology Research Interview (PERI) and other social network variables assessed independently. They found significant correlations between axis V adaptive functioning and both social and occupational variables, with occupational factors predominating. Westermeyer and Neider (15) found highly significant negative correlations between axis V ratings and two separate components of social networks—number of people and number of separate social groups—among patients with substance abuse. Finally, Rey et al. (7) reported that in their samples of adolescents, axis V functioned similarly to independent ratings of premorbid functioning and less like measures of social competence or present functioning.

In a series of analyses, Gordon and associates have examined the relation between axis V ratings and treatment status. Initially, Gordon et al. (16, 17) developed a measure called the "strain ratio," which is the ratio of axis IV ratings of severity of psychosocial stressors to axis V ratings, transformed in such a way that higher ratings indicate better adaptive functioning. They found that length of inpatient hospitalization was correlated with higher strain ratios: when patients' rescaled levels of functioning exceeded their scores on axis IV, they tended to remain in the hospital for a shorter period. Subsequently, Gordon and Gordon (18) reported predictable differences in axis V ratings between chroni-

cally ill state hospital patients, long-term inpatients, short-term inpatients, and outpatients.

Mezzich et al. (19) found that ratings of highest level of adaptive functioning in the past year correlated 0.27 with the decision to admit a patient for inpatient treatment from a walk-in clinic. These investigators found a greater correlation ($r=0.45$) between impairment in current adaptive functioning, measured over the preceding month, and inpatient disposition.

In the first of two prospective studies of the ability of axis V ratings to predict outcome, Mellsop et al. (20) found a significant relation between preadmission adaptive functioning as measured by axis V and symptomatic outcome at 6 months among inpatients. They also found, however, an even greater relation between outcome and functioning as measured by the self-report Social Adjustment Scale. In the second study of predictive validity, Beiser et al. (21) found that axis V was a powerful predictor of which patients who received a diagnosis of schizophreniform disorder early in a psychotic episode would, in fact, recover within the 6 months stipulated by *DSM-III* and which ones would not recover, necessitating a change in diagnosis to schizophrenia.

DSM-III-R Axis V

There are no currently published studies on the Global Assessment of Functioning Scale of *DSM-III-R*, but a number of the reports we have mentioned and two additional studies have some bearing on the changes in the adaptive functioning construct in *DSM-III-R*. The two major changes in concept are 1) the provision for rating both highest level of adaptive functioning in the past year and current functioning and 2) the inclusion of symptom severity, as well as indicators of social and occupational functioning, in the ratings.

With respect to the first change, Skodol et al. (9) found few differences between social and occupational functioning measured over the past year as compared to measured over the past month when these were correlated with axis V ratings of highest level of functioning in the past year. Rey et al. (7) also found a greater relation between axis V and independent ratings of pre-morbid, rather than present, functioning. The analyses of Fabrega et al. (13) and Mezzich et al. (6), however, point to the potential importance of current functional impairment as a consideration in diagnosis and treatment planning.

With respect to the second change, several different groups have attempted to divide axis V into its component parts and examine each component separately. In the study by Trzepacz et al. (11), separate ratings of current occupational, family, and social functioning all bore the same relation to delirious versus nondelirious diagnostic status as did the overall axis V rating. On the other hand, Mellsop et al. (20) observed some variations in the relation between three similar factors and outcome prediction and suspected that global ratings of adaptive functioning masked significant variability.

Beiser et al. (21) believed that the inclusion of symptoms in *DSM-III-R* axis V would undermine its ability to discriminate schizophreniform from schizophrenic patients. Gordon et al. (22) showed that symptom improvement and functional improvement, as measured by axis V, did not go hand in hand in discharged patients followed in outpatient treatment over time. And finally, Skodol et al. (23) demonstrated that symptoms had a larger effect on axis V ratings, in terms of explained variance, than adaptive functioning variables and tended to detract from the latter's significance. Although the effect of symptom measures on explained variance may be taken as support for changing axis V into the Global Assessment of Functioning Scale, the change also may make axis V more redundant with axis I diagnoses. If a major objective of a multiaxial approach is the quasi-independent assessment of different domains relevant to a comprehensive psychiatric diagnosis, then explicit inclusion of symptoms in the axis V ratings would seem to defeat this purpose.

STRENGTHS AND WEAKNESSES OF AXIS V

This review suggests that axis V is a reasonably valid measure of adaptive functioning, limited in part by its modest reliability. In addition, some problems have been identified with the changes introduced at the time of the revision of *DSM-III*. For example, there is mixed evidence on the value of obtaining measures of functioning during two time periods (i.e., past month and past year). (As might be expected, the value seems to depend on the nature of the question being asked, suggesting that assessments in both time periods have merit. Consequently, there is no great pressure to change axis V, again, to a rating of a single period.) Two other problems, however, are believed by some to limit the utility of axis V in *DSM-III-R*. In particular, there is concern that 1) the assessment of functioning is attributed to mental impairment alone and 2) one axis combines measures of psychological, social, and occupational functioning. In the first instance, it may be impossible to disentangle the combined limitations imposed by mental and physical impairments; in the latter, it may be too difficult to assess these distinct domains of functioning with a global measure.

These problems may be related. The progenitor of the Global Assessment of Functioning Scale, the GAS, was designed as a global measure of psychopathology, focusing heavily on current psychological functioning. As such, it was logical to focus on functioning related to mental disorders alone. When the global GAS approach is used more broadly, emphasizing social and occupational functioning over the past year, it may be much more problematic to attribute functioning to a mental disorder alone. Furthermore, when the GAS model is used in general medical settings or with elderly patients who have multiple impairments, it is even more difficult to make such attribution reliably (personal communication, E. Caine).

The combination on a single axis of measures of psychological, occupational, and social functioning is problematic for two reasons: 1) it violates the principle of a multiaxial system in which each axis "refers to a different class of information" (*DSM-III-R*), and 2) it may also confuse raters because of the complexity of making a single rating which integrates three different dimensions that do not always vary together. As we have noted, there is evidence from Skodol et al. (9, 23), supported by the findings of other studies (20–22), that ratings on axis V are highly correlated with those on axis I, indicating that axis V does not provide a sufficiently independent class of information. In addition, other investigators (24–27) have indicated that psychological functioning often does not correlate well with social and occupational functioning. Although a recent set of studies by Liberman (28) suggest a significant relation between symptom measures and occupational functioning, it is a relationship mediated by functional impairments in the capacity to work (such as limitations in social interaction and activities of daily living).

Before deciding to recommend retaining the Global Assessment of Functioning Scale for axis V or changing to another measure, we turned again to the literature.

MEASURES OF SOCIAL FUNCTIONING

We reviewed the literature on measures of social functioning in an effort to find out what other measures might be used as models for axis V. Our review relied heavily on two articles: "The Assessment of Social Adjustment: An Update" by Weissman et al. (29) and "Functional Assessment in Rehabilitation" by Wallace (30). Promising instruments were viewed in more detail from their original sources. Although we reviewed each of the instruments for depth and breadth of measures, appropriate target population, and psychometric properties, the special criteria we used to evaluate these scales for possible inclusion in axis V focused also on simplicity ("user friendliness") and unidimensionality (i.e., involving a single class of information). The instruments reviewed in the articles by Weissman et al. and Wallace are shown in table 1; citations of the original references are provided. The reviews of each of these instruments are summarized in table 1 along several dimensions, including psychometric properties and method of scoring. Each instrument is placed into one of seven groups on the basis of inclusion of symptoms in the instrument or schedule, depth and breadth of dimensions of functioning, and applicability to the general population (rather than to a specific clinical group).

As shown in table 1, group 1 consists of the Denver Community Mental Health Questionnaire and the KDS-15 Marital Questionnaire, which include symptom measures, do not include role performance measures (especially the Denver Community Mental Health Questionnaire), and focus on specific clinical groups (i.e., community mental health clinic clients and married couples). Group 2 includes the Katz Adjustment

Scale, Personal Adjustment and Role Skills Scale, Psychiatric Status Schedule, Psychiatric Evaluation Form, and Current and Past Psychopathology Scales. This group also includes symptoms, is somewhat more inclusive of areas of functioning than group 1, and is broadly applicable to the entire clinical population. It is similar to group 5, which includes the Social Behaviour Assessment Schedule and the Self-Assessment Guide, both of which are more detailed measures of functioning than the instruments in group 2. Group 3 includes the Rehabilitation Evaluation of Hall and Baker and the Community Living Assessment Scale, which do not include symptom measures, which focus on a narrow domain of functioning, and which principally apply to a limited population in 24-hour care. The Personal Resources Inventory and Interview Schedule for Social Interaction are in group 4; they do not include symptom measures, and they focus on a narrow range of functioning but are more broadly applicable than the instruments in group 3.

Groups 6 and 7 are similar. All of the instruments (Community Adaptation Schedule, Structured and Scaled Interview to Assess Maladjustment, Standardized Interview to Assess Social Maladjustment, Community Adjustment Profile System, Social Stress and Functioning Inventory for Psychotic Disorders, Social Functioning Schedule, and the various versions of the Social Adjustment Scale) measure a broad range of functioning without assessing symptoms. The social functioning scales from the PERI (27) and the Longitudinal Interval Follow-up Evaluation (56) were not included in either review and should be added to category 7. The same is true for the Role Activity Performance Scale (57). All are applicable to a broad population, and almost all give global ratings, but the Community Adaptation Schedule is judged by Wallace (30) to have limited information on its psychometric properties.

We refer the interested reader to the two review articles and the original material in the literature for a more comprehensive assessment of these instruments. Our brief review focuses on the suitability of alternatives to the Global Assessment of Functioning Scale for inclusion in *DSM-IV*.

Given our criteria of unidimensionality, the instruments in groups 3, 4, 6, and 7 should be considered as alternatives to the Global Assessment of Functioning Scale. Groups 3 and 4, however, cover too limited a domain of functioning, and group 4 is also limited in its applicability. The Community Adaptation Schedule (group 6) also might be eliminated because of limited psychometric data, leaving the instruments in group 7. If the criterion of unidimensionality is deemphasized, then groups 1, 2, and 5 also must be considered. Group 1 is a weaker choice because of limitations in range of functioning measured and applicability, as well as lack of a global measure. Groups 2 and 5 include many meritorious measures of symptoms and functioning. In fact, the GAS, the basis for the Global Assessment of Functioning Scale, is derived from the work of some of the same investigators who developed the instruments in group 2.

In terms of user friendliness, global ratings are given by instruments in groups 2, 3, 6, and 7. All of these ratings, however, are based on fairly extensive interview schedules or structured self-reports. In part, their structured formats make them reliable and recommend them for use in research. On the other hand, none of these measures could be regarded as simple enough for routine use in clinical practice.

OPTIONS

The approach to change for *DSM-IV* has been characterized as "conservative," requiring compelling arguments and extensive documentation to support alterations in the nosology (58). Although our review suggests a number of problems with the current Global Assessment of Functioning Scale, there are problems with all of the potential alternatives as well. Before considering a complete change in axis V, there should be evidence of severe problems with the Global Assessment of Functioning Scale and/or an outstanding new alternative. Considerable experience with the Global Assessment of Functioning Scale (and its predecessor, the GAS) and its apparent simplicity made it a choice for *DSM-III-R* and argue for its retention—with some significant modification. As we have noted, the principal limitations of the Global Assessment of Functioning Scale are 1) the combination of ratings of symptoms and functioning on a single scale and 2) the rating of functioning based on mental impairment alone rather than the combined effect of mental and physical impairments.

The Global Assessment of Functioning Scale could be modified to separate the rating of symptoms and psychological functioning from the rating of social and occupational functioning. We propose a field test of a modification of the current axis V scale. (See appendix 1 for an example of one modification.) We have divided the current Global Assessment of Functioning Scale into two separate scales, one to measure global symptomatology and psychological functioning, the other to measure social and occupational functioning. The modified scale in appendix 1 retains the same scale points and many of the anchoring descriptors that are used in the current Global Assessment of Functioning Scale. We hypothesize that this change will reduce confusion and improve the independence of the ratings of these domains. This hypothesis, as well as the reliability of the measures, should be assessed in a field trial of the modified scale. The results of the field trial may indicate a need for more elaborate anchoring descriptors, which could then be developed. If it is found that the modified Global Assessment of Functioning Scale shown in appendix 1 is more reliable, produces ratings on social and occupational functioning that are significantly more independent of axis I than the current scale ratings, and is more acceptable to clinicians who use it in the field trial, then the modified scale should be used as a substitute for the current scale.

TABLE 1. Measures of Social Adjustment and Functioning

Instrument	Inclusion of Symptoms
Group 1	Yes
Denver Community Mental Health Questionnaire (DCMHQ) (31, 32)	
KDS-15 Marital Questionnaire (KDS-15) (33)	
Group 2	Yes
Katz Adjustment Scale (KAS) (34)	
Personal Adjustment and Role Skills Scale (PARS) (35)	
Psychiatric Status Schedule (PSS) (36)	
Psychiatric Evaluation Form (PEF) (37)	
Current and Past Psychopathology Scales (CAPPS) (38)	
Group 3	No
Rehabilitation Evaluation of Hall and Baker (REHAB) (39)	
Community Living Assessment Scale (CLAS) (40)	
Group 4	No
Personal Resources Inventory (PRI) (41)	
Interview Schedule for Social Interaction (ISSI) (42, 43)	
Group 5	Yes
Social Behaviour Assessment Schedule (SBAS) (44)	
Self-Assessment Guide (SAG) (45)	
Group 6	No
Community Adaptation Schedule (CAS) (46)	
Group 7	No (except SSIAM)
Structured and Scaled Interview to Assess Maladjustment (SSIAM) (47, 48)	
Standardized Interview to Assess Social Maladjustment (SIASM) (49, 50)	
Community Adjustment Profile System (CAPS) (51)	
Social Stress and Functioning Inventory for Psychotic Disorders (SSFIPD) (52)	
Social Functioning Schedule (53)	
Social Adjustment Scale (SAS); Self-Report (SAS-SR); Version II (SAS-II) (54, 55)	

The modified scale's measure of social and occupational functioning is similar conceptually to the original *DSM-III* axis V measure of adaptive functioning. The modified scale's measure of global symptomatology and psychological functioning would be a new assessment. It might be included as a second rating on axis V or rated on a separate axis. It is likely that ratings on this measure will be highly correlated with axis I. To some extent it also may be redundant with the proposed

TABLE 1 (continued)

Depth	Scoring	Applicability	Psychometric Characteristics	Other Characteristics
Not much depth	Give specific and more general scores	Highly specific	Reliable and valid	
Little attention to role performance		Designed only for mental patients		
Looks only at marriage		Designed only for married couples		
Not much depth	Give specific and more general scores	Generally applicable	Reliable and valid	
Ignores many roles; does not discuss cause of problems				Short and simple; can be used with significant other
	Gives global rating			
Does not discuss cause of problems	Gives global rating			Flexible; includes probes; can be used with significant other
Does not discuss cause of problems	Gives global rating			
Does not discuss cause of problems	Gives global rating			
Not much depth	Give specific and more general scores	Highly specific	Reliable and valid	
		Designed only for institutionalized patients		Well explained; simple to use; easy to interpret
	Gives global rating	Designed for individuals in residential care facility	Should be further investigated	
Not much detail; look only at individual's support network	Give specific and more general scores	Generally applicable	Reliable and valid	
			Should be further investigated	
Very detailed	Give specific and more general scores	Generally applicable	Reliable and valid	
				Self-report; short
Very detailed	Gives specific and more general scores; also gives a global rating	Generally applicable	Reliability and validity need further investigation	Self-report
Very detailed	Give specific and more general scores	Generally applicable	Reliable and valid	
				Careful about interviewer bias; can be used with significant other
	Gives a global rating			Can be used with significant other
				For significant other
				Can be used with significant other
	Gives a global rating			Flexible; can be given to significant other; self-report available; good with psychotic patients

inclusion of severity ratings for each mental disorder (personal communication, J. Mezzich).

The instruments in group 7 should be examined further as potential substitutes in the future, especially if there are problems with the Global Assessment of Functioning Scale or its modification. If warranted by further examination, there should be a field trial of the best global measure or measures from group 7 for use in general clinical practice *without* a standardized schedule.

A simple modification in the instructions for rating the Global Assessment of Functioning Scale could address the other identified problem with axis V. As we have noted, when assessing certain patients, it is difficult (or impossible) to separate the effects of mental impairments from physical impairments contributing to limitations in social and occupational functioning. Axis V in *DSM-III* did not instruct the rater to make any such distinction. In contrast, the instructions for the Global Assessment of Functioning

Scale explicitly call for a rating of limitations of functioning due to mental impairments alone. We propose a field test of a modification of the instructions for the modified Global Assessment of Functioning Scale (Functioning) to assess social and occupational functioning due to the *combined* effects of mental and nonmental medical impairments (appendix 1).

CONCLUSIONS

The options under consideration by the Work Group on Multiaxial Issues include some combination of changes in the basic structure of the Global Assessment of Functioning Scale and in the instructions. Our review of the relevant literature suggests both of these potential modifications, following a conservative strategy for change. The final decision should be based on a field test of these recommendations. It is our hope that these modest changes will increase the utility and use of axis V.

In following a less conservative strategy for change, several other avenues of research and scale development are indicated. First, there is a need to study the impact of various approaches to training on the reliability of measures of social and occupational functioning. Second, our review suggests the need for different measures for different areas of functioning. The conservative strategy and requirement for simplicity, applicable to multiaxial diagnosis and DSM, may be overly limiting for valid and useful measurements of functioning. A more multidimensional approach to measuring social and occupational functioning in individuals with mental disorders may be superior. The research literature suggests numerous more complex measures. Further investigation may produce simpler measures of each of the multiple dimensions of functioning that could be used in practice as well as research.

Leaders in general medicine have called for the use of simple measures of functioning in routine clinical practice—to support the need for measures of clinical outcome (59–61). Feinstein et al. (62) warned of the problems associated with these needed measures, noting that the measures should be “sensible” as well as reliable and valid. The current Medical Outcomes Study (61) has been using a “short form” measure of several dimensions of functioning and health status (63) and has adapted it for use in assessing outcomes in a variety of clinical conditions, including depression (64, 65). The field of psychiatry has growing experience with functional assessment and the measurement of medical outcomes. We have the opportunity to be in the forefront of this important area of health care research and practice.

APPENDIX 1. Modification of the Global Assessment of Functioning Scale: Mental and Physical Impairments Functioning Scale (GAFS-M)

Consider social and occupational functioning on a hypothetical continuum of mental health-illness. Include impairment in functioning due to physical limitations as well as mental impairments. Use HIGHEST LEVEL OF FUNCTIONING IN PAST YEAR (i.e., highest level of functioning for at least a few months during the past year).

Code

- | | |
|----|---|
| 90 | Good functioning in all areas, interested and involved in a wide range of activities, socially effective |
| 81 | |
| 80 | No more than slight impairment in social and occupational functioning (e.g., missing a few deadlines or appointments) or school functioning (e.g., temporarily falling behind in school work) |
| 71 | |

70	Some difficulty in social or occupational functioning (e.g., frequent work absences, work occasionally incomplete or judged "not up to standards") or school functioning (e.g., occasional truancy, or theft within the household) but generally functioning pretty well; has some meaningful interpersonal relationships	40	Major impairment in several areas, such as work or school, family relations, judgment (e.g., avoids friends, neglects family, is unable to work; child frequently beats up younger children, is failing at school)
61		31	
60	Moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with co-workers, unable to complete work assignments, unsatisfactory work performance)	30	Inability to function in almost all areas (e.g., stays in bed all day; no job, home, or friends)
51		21	
50	Serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job at expected or prior level of performance)	20	Occasionally fails to maintain minimal personal hygiene (e.g., smears feces); unable to function independently
41		11	
		10	Persistent inability to maintain minimal personal hygiene; unable to function without harming self or others or without considerable external support (e.g., nursing care and supervision)
		01	

Judicial and Legislative Responses to Cost Containment

Lloyd I. Sederer, M.D.

Cost containment through reduction of insurance benefits and aggressive utilization review is increasingly risking the sacrifice of good clinical care in the pursuit of financial objectives. This article provides examples of judicial and legislative responses to perceived fiscal intrusions into clinical practice. Principles for asserting clinical goals in the cost containment process are also provided to assist in the inevitable negotiations and battles ahead.

(Am J Psychiatry 1992; 149:1157-1161)

The cost of health care in the United States is now perennially exceeding the growth of the national economy. Furthermore, vast numbers of American citizens (estimates are 34-37 million people) have no access to health care insurance benefits, and tens of millions more are underinsured. Finally, there is no national or overarching health care policy to shape the future nature of this health care system (1-6). As a consequence, a variety of measures have been undertaken as ostensible solutions to this highly problematic triad of circumstances.

For clinicians, patients, and families, the most disturbing "solutions" have been efforts to reduce health care costs, especially psychiatric and substance abuse costs, by constricting insurance benefits and by aggressive utilization review. Effective utilization review can protect patients from unnecessary care and can allow for flexible use of benefits. However, an explosively growing industry of managed care organizations coupled with limited and potentially decreasing insurance benefits threatens to sacrifice patient care on the altar of presumed fiscal responsibility (7, 8).

This article provides illustrative and important (but by no means exhaustive) examples of the judicial and legislative initiatives that have attempted to reassert clinical priorities in the cost containment process. The

cases and laws summarized here, some involving psychiatry and some involving general medicine, are guideposts as we try to maintain standards of professional practice in this era of cost containment.

UTILIZATION REVIEW

Utilization review is the process of determining whether medical care is needed and at what level of intensity (e.g., inpatient versus outpatient, surgical versus medicinal) (9). Utilization review is a primary activity of managed care organizations, principally through prior approval and concurrent review.

Judicial Cases

Utilization review practices of third-party insurance companies and fourth-party managed care organizations have been challenged in the courts since the 1970s. In the court cases summarized here, the conflict between clinicians and proponents of cost containment is well illustrated.

Wickline v. State of California (10) is regarded as a landmark case in utilization review, although it did not involve psychiatric illness. Lois Wickline was covered by Medi-Cal (Medicaid of California). In 1976 she received utilization review approval for admission to a California hospital for surgical treatment of obstruction of the terminal aorta (Leriche's syndrome). On the day of her surgery, she had to undergo a second operation for a blood clot that had formed in the graft. Five days later she underwent lumbar sympathectomy for

Received June 8, 1991; revision received Dec. 10, 1991; accepted Jan. 17, 1992. From McLean Hospital and the Department of Psychiatry, Harvard Medical School, Boston. Address reprint requests to Dr. Sederer, McLean Hospital, 115 Mill St., Belmont, MA 02178-9106.

pain symptoms secondary to vessel spasm. Because her insurance approval was to expire 4 days later, her doctors asked for an 8-day extension. The utilization review organization approved 4 days, which her physicians did not appeal. She was discharged after the 4-day extension. Nine days later Mrs. Wickline required emergency readmission for an infection and clotting at the site of the graft. She went on to require below-the-knee amputation of her right leg, and when healing did not proceed, she had to undergo above-the-knee amputation.

Mrs. Wickline, instead of seeking damages from her doctors, sued the State of California and its medical review organization. In trial court she was awarded \$500,000. In appellate court the state was not regarded as negligent, and the lower court's decision was reversed. The Supreme Court of California declined to review the case, thereby rendering the appellate court's decision final.

Two critical lessons emerge from the *Wickline* case. The first is that medically inappropriate decisions which derive from cost containment practices can be torts. The court stated that a "patient who is harmed when care which should have been provided is not provided should recover from all responsible for deprivation of care, including, when appropriate, a health care payer." The court added, "Third party payers of health care services can be held legally accountable when medically inappropriate decisions result from defects in designs or implementation of cost containment mechanisms." However, there is a second crucial lesson, which is best articulated by also quoting the court: "A physician who complies without protest . . . when his medical judgment dictates otherwise, cannot avoid his ultimate responsibility for his patient's care." In effect, the *Wickline* case broke ground by holding the insurer liable, but only if the physician has fully pursued all the appeals processes available to him or her. This is clearly a practice guideline for physicians rendering care and encountering denial of insurance coverage.

Hughes v. Blue Cross of Northern California (11) was upheld in appellate court in 1988 and held Blue Cross of Northern California responsible for \$150,000 in compensatory damages and \$700,000 in punitive damages. The court found that Blue Cross was engaged in egregious utilization review practices: only fragments of important records were obtained; there appeared to be only a cursory review of the records; the reviewing consultant disclaimed any obligation to pursue diligently the materials on the case; and there were uninformative follow-up letters to the physicians involved regarding the denial of benefits. Hughes was a 21-year-old, seriously psychiatrically ill man whose history began in 1981 with a hospitalization after a drug overdose and self-inflicted stab wounds to the abdomen with a screwdriver. The patient had multiple hospitalizations over the course of a year and had a deteriorating course. Portions of two hospitalizations were subsequently denied coverage by Blue Cross, without their having obtained adequate records and without their explaining the medical grounds for the denial. The court decided

that the insurer acted in bad faith by behaving with "conscious disregard of the insured's rights." It was this breach of the covenant of good faith and fair dealing that resulted in the heavy punitive damages. Clinicians, patients, and families can and should expect careful and diligent utilization review by payers.

Insurers, however, are not bound to follow strictly the clinical opinion and treatment plan of the attending physician (12). This creates a sometimes useful exchange of clinical ideas but places the patient in the position of having to pay for what is usually prohibitively expensive treatment (e.g., hospitalization) if his or her doctor loses the debate with the utilization reviewer. Timely review processes, required by contract or law, would help to minimize this frequent problem.

Wilson v. Blue Cross of Southern California (13) is a case of particular importance to practicing psychiatrists, because it is recent and it involves the death of a patient discharged because insurance coverage was denied. In 1983 Howard Wilson was admitted to a Los Angeles hospital with diagnoses of major depression, drug dependence, and weight loss. His admitting physician recommended 3-4 weeks of hospital care. Wilson was discharged 10 days after admission, when his insurer denied benefits and the patient and family had no money to support further inpatient treatment. Three weeks later Mr. Wilson took his life by overdose. His parents subsequently sued Blue Cross of Southern California and their review organization, Western Medical Review. The case had a summary judgment of dismissal in Superior Court in Los Angeles. On appeal, the court held that the contractor (namely, the insurer) could be at least partially "liable if negligent conduct was a substantial factor in bringing about the suicide." The appellate court reversed the lower court and remanded the case back to trial court, where it must be retried. This case may be another crucial precedent in holding managed care organizations liable for adverse outcomes secondary to denial of insurance benefits.

Varol v. Blue Cross/Blue Shield (14), concluded in 1989, is an important warning to physicians contracting under managed care plans. Although the court held that this case could not go forward because of an ERISA preemption (the Employment Retirement Income Security Act places certain insured organizations under federal rather than state statute), the court used the occasion to speak firmly to physicians. In this case a group of psychiatrists providing care under a Blue Cross/Blue Shield managed care contract for General Motors alleged that their contract impinged on the proper treatment of patients. The court retorted that a contract is binding and must be either terminated or honored, not altered by the court. To quote the court: "How can doctors challenge the provisions to which they agreed? . . . challenge only the provisions they do not like? . . . ask the court to modify the contract to their liking?" Furthermore, "plaintiffs are saying in effect, 'since I am weak in my resolve to afford proper treatment, the Blue Cross/Blue Shield preauthorization program would induce me to breach my ethical and legal duties . . . The

court must protect me from my own weakness' " (14, p. 833). Clearly, the court ruled that doctors are to be held to their contractual arrangements.

Finally, a case recently decided in a U.S. District Court, *Nazay v. L. Miller/Bethlehem Steel* (15), challenged the legality of prior approval, which is crucial to virtually all types of managed care. Nazay was a retired employee who was held responsible by an insurer for 30% of the costs of his hospital care for heart disease because he had neglected to obtain prior approval. Because his care was regarded as medically necessary, the court regarded the penalty as "arbitrary and capricious." The case is now under appeal. If the decision is upheld, a precedent would be established that would outlaw prior approval of medically necessary care by managed care plans.

Legislation

At the time of this writing, 19 states have enacted some type of utilization review legislation. Maryland was the first to enact such legislation; the states that have followed are Arizona, Connecticut, Florida, Georgia, Hawaii, Kentucky, Maine, Minnesota, Mississippi, Missouri, Montana, North Carolina, North Dakota, Oklahoma, Pennsylvania, South Carolina, Texas, and Virginia.

Many common provisions exist among these state laws. Articulated appeals processes, accessibility of reviewers to doctors and patients, clinically trained reviewers, and confidentiality of records tend to be basic regulatory requirements. Open and available review criteria and a requirement that only a physician can render an insurance denial are standards that have been established in some states (e.g., Connecticut, Missouri, and North Dakota have the standard for open review criteria, and Hawaii, Texas, and Montana have the standard of denial by a physician only).

Many other states are considering legislation to regulate the practices of managed care organizations and insurers providing utilization review. Utilization review companies continue to oppose these legislative initiatives and instead offer voluntary self-regulation through a nationally based accreditation association (16). In one form or another, it appears likely that utilization review will be increasingly standardized and regulated in the years to come.

INSURANCE BENEFITS

Cost containment has also been pursued by reducing the insured population's benefits. Patients, families, and professionals in turn have sought judicial and legislative remedies for perceived injustices.

Judicial Cases

Benefits for psychiatric disorders and substance abuse generally have been differentiated from benefits

for medical/surgical disorders, with less coverage being the rule (e.g., fewer covered days and dollars, higher copayments and deductibles). Several court cases have challenged this unfavorable and stigmatizing differentiation, particularly for the severely mentally ill.

Arkansas Blue Cross/Blue Shield v. Doe (17) was upheld in appellate court in 1987. In this case, a man whose daughter, a minor, had bipolar disorder sued Blue Cross/Blue Shield for the benefits that he had not obtained because of the limit on benefits under the mental health provisions of his policy. The principal argument in the case was that bipolar disorder is a biological disorder, and therefore the benefits should be on a par with those received for any other physical condition. The Arkansas court held that, indeed, bipolar disorder is a physical condition and that the insured was entitled to the benefits for a physical, not a mental, disorder. A case brought by the father of a patient against the Mutual Insurance Company of New York and B'nai B'rith (the *Rosenthal* case) is similar to the Arkansas case and was settled in late 1990 out of court (18).

Kunin v. Benefit Trust Life Insurance Co. (19) was a case in which a father brought action to recover benefits for the treatment of his autistic son at UCLA Neuropsychiatric Institute. The boy was admitted in 1986 for 30 days, and \$55,000 in hospital charges accumulated. The psychiatric benefits were limited to \$10,000. The father alleged that autism is a biological disorder. The court held that autism should be covered under medical, not mental, benefits and ordered payment by the insurer. The *Doe*, *Rosenthal*, and *Kunin* decisions are important precedents in a growing effort to establish parity of psychiatric and medical benefits.

Doe v. Guardian Life Insurance Co. et al. (20) was a class action suit brought by the Chicago National Depressive and Manic-Depressive Association in Cook County Circuit Court against two of the largest insurance corporations operating in Illinois, Guardian Life and Travelers' Insurance. The association alleged that manic-depressive illness is a "physical or biological illness," and, consequently, payments for the treatment of this mental illness should be equal to those for physical or biological illnesses. This case was dismissed by the court because of a technical problem, namely, that the court regarded the National Depressive and Manic-Depressive Association as "lacking any standing to sue under ERISA." The substance of the case was never addressed. Nevertheless, this was yet another effort to seek nondiscriminatory benefits for major mental illnesses.

Another case that failed in court is that of *Teti v. US Healthcare* (21). US Healthcare is a large managed care organization with significant activity in Pennsylvania, where this case was filed under the Racketeer Influenced Corrupt Organization Act. Awards under this act include treble damages and lawyers' fees. The plaintiff alleged that US Healthcare engaged in fraudulent behavior by misrepresenting its services (false advertising), because it failed to disclose financial compensation arrangements with physicians and the available specialty and hospital services. The plaintiff argued that

these arrangements discouraged the provision of services and that, consequently, consumers could not realize the benefits they had purchased. This case was dismissed by the court in December 1989.

Finally, the potential for a managed care organization to reduce union-negotiated health benefits was alleged in a class action suit against the state of Ohio (22, and personal communications from the Ohio District Branch of APA). The state of Ohio, which has 50,000 employees, had contracted for American Biodyne to manage its mental health and substance abuse benefits, anticipating that this would save \$4.5 million. The plaintiffs alleged that the service plan devised by American Biodyne would not correspond to the benefits that had been worked out in collective bargaining. In addition, there were many concerns among clinicians that American Biodyne's method of conducting its utilization review would be intrusive and would interfere with patients' access to care. Litigation was dropped because of the high costs of pursuing the case and because of the anticipated difficulties in proving that "intrusive case review" reduced the union-negotiated benefits package. The *Teti* case and the class action suit against Ohio failed to limit, through case law, the financial, referral, and utilization practices of managed care organizations.

Legislation

In a recessionary economy and in a time of belt tightening, it is sometimes an achievement to retain benefits. It has been especially heartening, therefore, to see expansion of benefits, which has occurred in two entitlement programs.

A remarkable coalition of interest groups came together in 1990 to bring about the progressive expansion of Medicaid benefits to all poor children. By the year 2001, all children who are eligible for Medicaid will be covered to the age of 18 (23). The federal government, the Health Insurance Association of America (representing the insurers), the National Association of Children's Hospitals, the National Association of Manufacturers, the American Medical Association, the Americans for Democratic Action, the American Hospital Association, the American Academy of Pediatrics, and Blue Cross/Blue Shield fashioned an alliance to bring this legislative effort to fruition. Perhaps this broad alliance of interest groups will have an opportunity to help legislate a national health insurance policy for all adults after the 1992 national election.

The second example of expansion of benefits, affecting psychiatry, involved the expansion of Medicare ambulatory care benefits from \$500 initially to \$1,100, then to \$2,200, and then, finally, to elimination of any benefit cap. This has been the only recent expansion of any type of Medicare benefit. Increased understanding of the biological bases of certain mental illnesses and reduction of stigma were instrumental in APA's achieving these gains.

Important legislative initiatives for insurance cover-

age for mental illness which is equal to that for medical/surgical disorders are also underway. Three states—Texas, Maine, and Maryland—have passed laws requiring that "biologically based" mental disorders have parity coverage. Although the states vary in their designations of the disorders to which the laws apply, all three include schizophrenia, major depression, and bipolar disorder. In 1989 California passed a nondiscriminatory coverage bill for five mental disorders, but this has not been implemented. In California a universal access bill, recently filed, does incorporate parity coverage for severe mental disorders (24, and minutes of the June 8–10, 1991, meeting of the APA Joint Commission on Government Relations). Other states and mental health advocacy organizations may want to pursue such groundbreaking parity legislation.

DISCUSSION

Faced with a recessionary economy and global competitive concerns, business and government in this country have no choice but to seek expense reductions. Health care has been particularly vulnerable to such reductions because of its robust growth and historical tendency (culturally supported) to do as much as possible. The economic shibboleth of the latest cost containment efforts in this country is managed care. An industry that promises to reduce costs has erupted. However, insurers and managed care organizations do not work for patients, and they do not work for families. These companies are employed by business and government to administer and manage health care benefits. In contracts in which strict budgetary controls apply (such as managed care), the insurer/managed care organization must contain costs or it will either lose its contract or suffer financial loss. As a consequence, these companies are inherently in conflict with doctors and hospitals who operate under a traditional medical ethic in which their primary responsibility is to the patient (not the dollars).

The utilization review litigation and legislation reviewed in this article highlight this conflict. Patients, families, and clinical care providers have gone to court to protect their interests. Legislative initiatives have sought to create responsible practices for utilization review organizations. Unless cost control is checked by litigation and regulation, it is likely to compromise patient care.

The benefits litigation and legislation reviewed in this article have sought to protect patients and families from discriminatory practices. Unless benefits for psychiatric and substance abuse disorders are properly recognized as essential and on a par with general medical benefits, the care of patients with these disorders will be undermined and progressively diminished.

The battle between costs and care is not new. Recent fiscal and political pressures, however, have intensified and will intensify this battle. As clinicians, we have principles that we can use to guide us in the years to

come. These principles apply in our professional practice, in court actions, and in legislative endeavors.

Fundamental to these principles is the recognition that cost containment cannot be at the expense of patients and, consequently, that responsible managed care must primarily attend to clinical decision making, not fiscal decision making. Open, professionally developed standards of utilization review (practice guidelines), rendered by credentialed professionals, must replace proprietary, secretive decision making. And no professional reviewer should receive incentives to deny care. Liability for adverse clinical outcomes secondary to negligent utilization review practices must continue to be aggressively sought by patients and families. Psychiatric and substance abuse benefits must be protected from elimination as employers seek low-cost policies (25, 26). Moreover, these benefits, especially for the severely mentally ill, should have parity in days, dollars, and deductibles with general medical and surgical benefits. Finally, every effort must be made to educate patients, families, employers, and government about mental illness and its true costs, especially if it is not covered and not treated. It is only by further destigmatizing mental illness and by demonstrating the efficacy of available treatments that mental health professionals will acquire the allies necessary to emerge successfully from the battles ahead.

Association of β -Endorphin With Specific Clinical Symptoms of Depression

Denis F. Darko, M.D., S. Craig Risch, M.D.,
J. Christian Gillin, M.D., and Shahrokh Golshan, Ph.D.

***Objective:** Abnormalities in plasma concentrations of β -endorphin-like immunoreactivity (β -endorphin) have been reported in depressed patients. This study was done to test the hypothesis that specific clinical characteristics of depression are associated with plasma β -endorphin concentration. **Method:** Plasma β -endorphin was evaluated in 20 depressed patients diagnosed according to DSM-III-R and in 23 age- and sex-matched comparison subjects, and each was evaluated with the structured Schedule for Affective Disorders and Schizophrenia (SADS). Twelve SADS items involving dysphoric mood and related symptoms were chosen for analysis. **Results:** Within the group of all 43 subjects and within the depressed group, β -endorphin level correlated significantly with psychic anxiety and with phobia. In the depressed group only, β -endorphin also correlated significantly with obsessions/compulsions. Concentration of β -endorphin was not significantly correlated with score on the Hamilton Rating Scale for Depression or Beck Depression Inventory or with scores on other SADS symptom items, including somatic anxiety, insomnia, subjective anger, overt anger, agitation, psychomotor retardation, panic attacks, appetite loss, or total weight loss. In the group of 23 comparison subjects, β -endorphin did not correlate with Beck or Hamilton depression score or with any of the SADS clinical variables. **Conclusions:** High levels of plasma β -endorphin may be associated with more severe anxiety, phobia, and obsessions/compulsions in depressed patients.*

(Am J Psychiatry 1992; 149:1162-1167)

Beta-endorphin is a 31-amino-acid hormone released by the pituitary into the systemic circulation in response to various psychological and physiological stimuli (1, 2). High basal plasma levels of β -endorphin and greater than normal secretion of β -endorphin in response to cholinergic stimulation have been observed in previous studies of depressed patients (3, 4), although not in all (5). Adults with affective psychiatric illness and early parental loss have been found to have higher resting plasma levels of β -endorphin than do healthy

comparison subjects with early parental loss (6), and a lower than normal total β -lipotropin/ β -endorphin secretory response after infusion of corticotropin-releasing factor has been found in depressed patients (5). Other studies (7-9) have shown nonsuppression of plasma β -endorphin after dexamethasone administration in depressed patients in whom dexamethasone also did not suppress cortisol, even in patients whose baseline β -endorphin levels were not higher than normal. Postdexamethasone levels of cortisol and β -endorphin were strongly positively correlated (8, 9).

In the present study we tested the hypothesis that high degrees of specific clinical characteristics (symptoms) of depression are associated with higher than normal plasma levels of β -endorphin-like immunoreactivity (referred to here as " β -endorphin"). Using the items involving dysphoric mood and related symptoms from the structured Schedule for Affective Disorders and Schizophrenia (SADS) interview, we examined the following 12 clinical characteristics of depression: somatic anxiety, psychic anxiety, phobia, insomnia, subjective feelings of anger, overt expression of anger, agitation, psychomotor retardation, panic attacks, obsessions/compulsions, appetite loss, and total weight

loss. Concentration of β -endorphin, severity of depressed mood, and these 12 symptoms were measured in 20 depressed patients and 23 age- and sex-matched comparison subjects.

METHOD

Subjects

The subject group comprised 43 subjects, 20 patients and 23 age- and sex-matched (all male) normal comparison subjects. The patients ranged in age from 29 to 71 years, and the comparison subjects' ages ranged from 31 to 68 years; their mean ages were 43 (SD=11) and 44 (SD=10), respectively ($t=-0.30$, $df=41$, $p=0.8$). They were hospitalized of clinical necessity but on a voluntary basis. All of the patients in the study gave informed consent.

Each patient completed a SADS interview (10) conducted by a research fellow in psychiatry. Twelve individual items from the SADS section on dysphoric mood and related symptoms were chosen. Eight of these items have an interval rating of severity and are parametric variables; the remaining four are nonparametric categorical variables. These items were used in the analyses. (SADS dysphoria items that describe core dysphoria/depression symptoms were not used. Subjective feelings of depression, negative evaluation of self, and similar SADS items were not included because they are so uniformly present in all depressed patients that we felt they would poorly discriminate depression subtypes.)

Research diagnoses were made in a consensus meeting of three psychiatrists and were based on the *DSM-III-R* nosologic system. The diagnoses of the 20 patients were as follows: major depression, recurrent ($N=13$), major depression, single episode ($N=3$), and bipolar disorder not otherwise specified (bipolar II) ($N=4$). All of the patients were currently depressed. Severity of depression was measured with the clinically objective 21-item Hamilton Rating Scale for Depression (11) and the subjective 21-item Beck Depression Inventory (12).

The patients' diagnoses of substance dependence were as follows: no history of alcohol or other substance abuse or dependence ($N=10$), diagnosis of alcohol dependence ($N=4$), alcohol dependence, in remission ($N=2$), alcohol abuse ($N=2$), alcohol abuse, in remission ($N=1$), and amphetamine dependence, in remission ($N=1$). The physical health of each patient was assessed through medical history, physical examination, CBC with WBC differential count, CHEM 20 blood chemistry profile, measurement of serum cholesterol and triglyceride levels, thyroid studies (T_3 , T_4), rapid plasma reagin test for syphilis, urinalysis, and ECG. Patients with medical histories or conditions that may have affected this study were excluded. Some of the subjects involved in this study also volunteered for other studies, which have been described elsewhere (13–18). Although all of the patients had previously

been treated with medication, all were hospitalized and had been free of medication and of alcohol and other substances of abuse for at least 14 days before this study. None of the patients had been treated with fluoxetine, which has a long half-life, before the study.

The 23 comparison subjects were medically and psychiatrically healthy and were recruited from a large metropolitan area. The comparison subjects were not admitted to the hospital, were not currently mentally ill, and had no history of mental illness according to SADS interview. The physical health of each comparison subject was assessed through medical history and CBC with WBC differential count.

β -Endorphin Assay

With standard clinical technique, venous blood was drawn into EDTA anticoagulated tubes. Three different protocols for blood drawing were used over the total time of the study. For 45% of the patients ($N=9$) and 40% of the comparison subjects ($N=9$), a single venipuncture in an antecubital fossa vein provided the single sample used. For 35% of the patients ($N=7$) and 30% of the comparison subjects ($N=7$), a butterfly needle was placed in a forearm vein, and three samples were drawn at 30, 45, and 60 minutes after needle placement. For 20% of the patients ($N=4$) and 30% of the comparison subjects ($N=7$), a blood sample was drawn immediately after butterfly needle placement, followed by samples at 30, 45, and 60 minutes. When multiple samples were drawn, the average β -endorphin level was used in the analysis. No time effect was observed for subjects from whom multiple samples were drawn. The plasma was collected by centrifugation of the blood samples at 400 g for 15 minutes, and it was kept frozen at -80°C until thawed for the β -endorphin radioimmunoassay.

The β -endorphin was measured by using the Nichols solid-phase iodine-125 two-site immunoradiometric assay. All samples were assayed in duplicate and within the same assay. The intra-assay coefficient of variation was 4.4%. The sensitivity of the assay is 10 pg/ml with a 16% cross-reactivity to human β -lipotropin. Two of the depressed patients had β -endorphin levels that were much higher than the others. These samples were assessed again, and similar values were obtained.

Statistical Analysis

The 20 patients and 23 comparison subjects were included in the analyses. For all analyses, a value of $p<0.05$ was considered significant. Differences in degrees of freedom reflect occasional missing data. (Most of the missing data were for the comparison subjects; the majority of these subjects were completely asymptomatic.) Because of the two patients with high β -endorphin levels, the β -endorphin data (in picograms per milliliter) did not fit a normal distribution. After consultation with a statistician, we log normalized the data, and the \log_{10} of each β -endorphin value was used in the

TABLE 1. Levels of β -Endorphin and Continuous Symptom Variables of 20 Depressed Patients and 23 Comparison Subjects

Variable	Depressed Patients		Comparison Subjects		t Test for Independent Samples

^aSpearman's rank-order correlation coefficient for nonparametric (categorical) variables.

statistical analyses. All statistics were calculated by using standard statistical programs (19, 20).

We used t tests for independent samples to test for the significance of the between-groups differences in the continuous variables, and the Mann-Whitney U/Wilcoxon rank sum W test or the Kruskal-Wallis one-way analysis of variance (ANOVA) and chi-square analysis were used for between-groups differences in the categorical variables (panic attacks, obsessions/compulsions, appetite loss, and total weight loss).

Parametric correlations of the continuous variables were calculated by using Pearson's correlation coefficient (r), and nonparametric correlations of the categorical variables were calculated with Spearman's rank-order correlation coefficient (r_s).

RESULTS

Characteristics of the two groups are shown in table 1. The Hamilton and Beck depression scores of the two groups were markedly and significantly different. Although the patients had a higher mean plasma β -endorphin level than the comparison subjects, the difference did not reach significance.

There were significant differences in the scores of the two groups on 11 of the 12 SADS mood items that clinically characterize depression; the patients had significantly more severe somatic anxiety, psychic anxiety, insomnia, subjective feelings of anger, agitation, psychomotor retardation, phobia, panic attacks, and obsessions/compulsions than the comparison subjects (see tables 1 and 2), but the patients did not have significantly more overt expressions of anger. Table 2 presents the results of the Mann-Whitney U/Wilcoxon rank sum W test for panic attacks, obsessions/compulsions, appetite, and weight loss. In addition to significantly more panic attacks and obsessions/compulsions, the patients showed significantly poorer appetite and greater total weight loss.

FIGURE 1. Relation of β -Endorphin Level to SADS Psychic Anxiety and Phobia Scores for Combined Depressed and Comparison Subjects (N=43)^a

^aSignificant correlations for both psychic anxiety ($r=0.42$, $df=41$, $p=0.03$) and phobia ($r=0.44$, $df=41$, $p=0.01$).

Within the group of all 43 subjects, β -endorphin concentration correlated significantly with psychic anxiety and with phobia (table 3 and figure 1). There was no significant correlation in this group between β -endorphin and score on the Hamilton or Beck depression scale or any of the other SADS items assessed, although a nearly significant difference was found for somatic anxiety, for panic attacks, and for obsessions/compulsions (table 3).

Within the group of the 20 patients, β -endorphin correlated significantly with psychic anxiety, with phobia, and with obsessions/compulsions (table 3 and figure 2). There was not a significant correlation between β -endorphin and Hamilton or Beck depression score or score on any of the other SADS items, although a nearly significant correlation was found for somatic anxiety (table 3). Within the group of all 23 comparison subjects, there were no significant correlations between β -endorphin and any of the SADS variables.

The 10 patients with histories of recent or past substance abuse were examined separately to see whether substance abuse history affected the interaction be-

FIGURE 2. Relation of β -Endorphin Level to SADS Obsessions/Compulsions Score for 20 Depressed Patients

tween β -endorphin and the relevant SADS variables. Age, Hamilton score, Beck score, β -endorphin level, and scores for somatic anxiety, psychic anxiety, phobia, and obsessions/compulsions were not significantly different between the patient groups with and without histories of substance abuse (see table 4). For the nonparametric variable, obsessions/compulsions, the results of Kruskal-Wallis one-way ANOVA and chi-square analysis were as follows: patients *with* substance abuse history, mean rank=10.17; patients *without* substance abuse history, mean rank=9.85 ($\chi^2=0.02$, $df=1$, $p=0.8$, n.s.). For the 10 patients with substance abuse histories, β -endorphin did not significantly correlate with any of the other variables ($0.1 < p < 0.7$).

DISCUSSION

This study, designed to test the hypothesis that plasma β -endorphin concentration in depressed patients is associated with specific clinical characteristics of depression, demonstrated a significant association between β -endorphin and three specific symptoms of depression as elicited by SADS interview—psychic anxiety, phobia, and obsessions/compulsions—and further suggested a possible association between β -endorphin and somatic anxiety and panic attacks.

Except for overt expressions of anger, the groups were significantly different in the symptoms chosen for study. There were no significant correlations between β -endorphin and the SADS interview items in the comparison group. This finding may support the specificity of the association between β -endorphin and anxiety, phobia, and obsessions/compulsions in the patients. An equally likely explanation, however, is that the narrow range of responses by the comparison subjects to the SADS items (most were scored zero) made it difficult to find significance on statistical tests for correlations.

The β -endorphin level was higher in the patient group but not significantly so. The literature is currently in conflict as to the true association between depression

TABLE 4. Age, β -Endorphin Level, and Selected Symptom Scores of 20 Depressed Patients With and Without Histories of Substance Abuse

Variable	With Abuse History (N=10)		Without Abuse History (N=10)		ANOVA		
	Mean	SD	Mean	SD	F	df	p
Age (years)	40	9	47	13	2.88	1, 17	0.1
Hamilton depression score ^a	23	8	26	13	0.002	1, 17	0.9
Beck depression score ^b	19	11	22	10	0.54	1, 17	0.5
Plasma β -endorphin level (pg/ml)	30.7	29.1	41.7	62.9	0.68	1, 17	0.4
Scores on SADS items							
Somatic anxiety	2.8	1.2	2.4	1.3	0.97	1, 16	0.3
Psychic anxiety	3.5	1.4	3.1	1.2	0.42	1, 16	0.5

and β -endorphin (3, 4, and 6 versus 5, 7–9). This conflict may have resulted from inattention to specific symptoms characterizing depression.

The results support the concept that β -endorphin is associated with specific clinical symptom clusters in depression, specifically symptoms associated with anxiety states. The results support the recent conceptualization of broad overlap between the depression spectrum of illnesses and the anxiety disorders. Anxiety and depression may have a common neurological substrate (21). In multivariate genetic analysis (22), no evidence could be found for genes that specifically affect symptoms of depression without also strongly influencing symptoms of anxiety. In a recent study of twin pairs (23), the results suggested an etiologic relationship between mixed major depression/anxiety disorders and major depression. Patterns of relationships of anxiety and depression to sociodemographic factors, prior psychopathology, and life events do not distinguish the two syndromes (24), and most widely used assessment methods do not measure anxiety and depression independently (25). Almost 40% of patients with *DSM-III* anxiety disorders simultaneously fulfill the criteria for a depressive disorder, mainly major depression (26). Lactate-infusion-induced decreases in β -endorphin have not distinguished subjects with major depression from subjects with panic disorder (27). Symptom overlap between depression and anxiety is large. The probability of symptom overlap in 150 psychiatric outpatients has been found to be 56%–60% (28). Finally, in a study of physically active versus sedentary men (29), the physically active men had a lower mean plasma β -endorphin level, lower anxiety index, and lower depression score than did the sedentary men. The literature regarding the relation of anxiety to depression has been reviewed by Stavrakaki and Varge (30).

Future studies may explore hypotheses concerning the specific role of β -endorphin in anxiety and phobia within the context of depression. Further, there is a growing interest in defining specific mental illnesses in terms of biological substrates rather than clusters of clinical symptoms or "phenotypic expression." The mapping of biological markers with clinical symptoms is a necessary step in this nosologic progress.

Neuroendocrine Effects of Intravenous Clomipramine in Depressed Patients and Healthy Subjects

Robert N. Golden, M.D., David Ekstrom, M.A., M.P.H., Terry M. Brown, D.O., Robert Ruegg, M.D., Dwight L. Evans, M.D., John J. Haggerty, Jr., M.D., James C. Garbutt, M.D., Cort A. Pedersen, M.D., George A. Mason, Ph.D., Jerry Browne, M.S., and Stanley W. Carson, Pharm.D.

***Objective:** Neuroendocrine challenge paradigms have been used to assess serotonergic systems in depression, but limitations in the specificity of many of these tests have been noted. In this study, the neuroendocrine responses to acute intravenous administration of the serotonin (5-HT) reuptake inhibitor clomipramine were assessed in depressed patients and matched control subjects. **Method:** Thirty hospitalized patients who met DSM-III-R criteria for major depression, and 30 healthy control subjects who were matched for age, sex, and season of year for the time of study, received 12.5 mg of intravenously administered clomipramine. **Results:** The depressed patients demonstrated significant blunting of prolactin responses to clomipramine, as well as trends toward blunted ACTH and cortisol responses. There was no difference between the patient and control groups in growth hormone responses, plasma clomipramine levels, or self-reports of side effects. **Conclusions:** These data support the hypothesis that depressed patients have abnormal neuroendocrine responses to the intravenous administration of the 5-HT reuptake inhibitor clomipramine. Further study is required to delineate the mechanisms responsible for the abnormal response to intravenously administered clomipramine in depression.*

(Am J Psychiatry 1992; 149:1168-1175)

Neuroendocrine challenge paradigms, which measure changes in plasma concentrations of serotonin (5-HT)-responsive hormones following exposure to 5-HT agents, have provided support for the indolamine hypothesis of depression (1). Several groups of investi-

gators have reported blunted prolactin responses to the 5-HT-releasing agent/uptake inhibitor fenfluramine and to the 5-HT amino acid precursor L-tryptophan in depressed patients (2-7). The cortisol response to the precursor 5-hydroxytryptophan is exaggerated in depressed patients, and the magnitude of the 5-hydroxytryptophan cortisol response is significantly correlated with severity of depression and suicidal activity (8, 9). Thus, depressed patients demonstrate abnormal neuroendocrine responsivity to pharmacologic stimulation of central 5-HT systems.

There are limitations, however, to the conclusions that can be drawn from these studies. First, the specificity of each of these probes for 5-HT systems has been questioned (10). Fenfluramine, for example, causes the release of dopamine and norepinephrine, as well as 5-HT (11), and can provoke substantial side effects (5), which might in turn stimulate the release of prolactin and other stress-responsive hormones. The *d*-isomer appears to be more specific for 5-HT effects and to have a milder side effect profile than the more commonly used racemic compound. However, in the only study to date to use *d*-fenfluramine (5), the compound was administered orally, thereby introducing the pharmacokinetic limitations described later in this paper. Trypto-

phan competes with tyrosine for a shared carrier mechanism to cross the blood-brain barrier (12) and thus might indirectly affect central catecholaminergic function by decreasing the availability of catecholamine precursor. Like fenfluramine, tryptophan can provoke side effects (7, 13), which might in turn stimulate stress-mediated release of prolactin and other neurohormones. The uptake of 5-hydroxytryptophan is not limited to 5-HT neurons (14, 15); 5-hydroxytryptophan can be converted into 5-HT in catecholaminergic neurons, leading to the release of catecholamines by displacement (16).

Pharmacokinetic factors can also affect neuroendocrine challenge tests, especially those which use the oral administration of the challenge agent (17). Since the neuroendocrine response data are collected at timed intervals, even relatively modest differences in the rate and/or degree of absorption of the challenge agent can contribute substantially to the variance observed. For example, the finding of blunted prolactin responses to tryptophan in depressed patients was not replicated in a study that controlled for plasma tryptophan concentrations in the data analysis (18).

The 5-HT uptake inhibitor clomipramine has considerable utility as a 5-HT challenge agent (19). Clomipramine is a potent inhibitor of 5-HT uptake at concentrations that have little effect on norepinephrine, although its demethylated metabolite does inhibit norepinephrine reuptake (20). Intravenous administration of clomipramine minimizes the problems seen with oral pharmacologic challenges regarding interindividual differences in rate and degree of absorption. Furthermore, this type of administration avoids the "first pass" effect of hepatic metabolism and thereby delays the formation of demethylated clomipramine and minimizes its effect on norepinephrine during the period of hormonal measurements (19). In the present study we chose to apply the clomipramine challenge test to hospitalized depressed patients and matched healthy control subjects.

METHOD

Subjects

This study was approved by the University of North Carolina School of Medicine Committee for the Protection of the Rights of Human Subjects. Oral and written informed consent was obtained from all subjects before their enrollment in the study. All potential subjects received a comprehensive medical evaluation, and only those who were free of any medical condition that could either jeopardize their safety or complicate the interpretation of the data were eligible to participate.

We studied 30 depressed patients (11 men and 19 women) who were hospitalized at a university hospital or on the university's clinical research unit at a psychiatric hospital. The mean age of the patients was 31.6 years (SD=10.5) (range=18–61 years). All patients were free of psychoactive medication for a minimum of 2 weeks at the time of testing. Diagnoses were assigned

by a board-certified psychiatrist (R.N.G.) and were based on all available clinical data, including the information generated by the semistructured Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (21), and without knowledge of the results of clomipramine testing. All patients met DSM-III-R criteria for major depressive episode; three patients had bipolar disorder, depressed phase, and the remaining patients met criteria for major depression, single episode (N=12) or major depression, recurrent (N=15). The mean score on the 21-item Hamilton Rating Scale for Depression (22) at baseline, before the test procedure, was 24.4 (SD=6.0) (range=16–40).

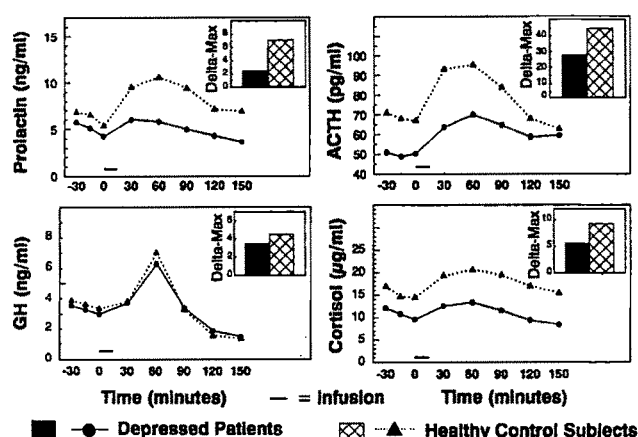

Healthy control subjects were recruited through printed advertisements distributed throughout the university campus and placed in the local and student newspapers. All potential control subjects underwent careful medical and psychiatric screening, including the administration of the SADS-L (21). Only subjects with no personal history of psychiatric illness and no family history of mood disorders and alcoholism were eligible. Control subjects were free of exposure to psychoactive medications and alcohol for a minimum of 3 weeks before the study. Eleven male and 19 female volunteers were selected in an effort to match the age of the depressed subjects as closely as possible. The mean age of the volunteers was 29.3 years (SD=7.1) (range=19–50 years). There was no significant difference in mean age between the groups ($t=0.96$, $df=50.9$, $p=0.34$).

The control subjects were admitted to the general clinical research center of a university hospital, where their infusion studies were performed. Because of recent reports of seasonal variation in some indices of serotonergic function (23), the studies of the control subjects were scheduled to match the seasonal distribution of the depressed patients' infusions. Fisher's exact test confirmed that there was no significant difference in the seasonal distribution of the testing of depressed and control subjects ($p=1.00$).

Infusion Procedures

Subjects were placed on a standard low monoamine, caffeine-controlled diet (24) for 3 days before the study. All subjects maintained a fasting state (except for water) beginning at midnight the night before the procedure and continuing until after the last blood specimen had been obtained. Subjects were awakened at 7:00 a.m. on the day of the infusion and were allowed to get out of bed at that time for a brief period to micturate if necessary. After that, each subject remained at strict bed rest until the procedure was completed. A research nurse determined that subjects did not fall asleep during the procedure.

An intravenous line was started at 8:30 a.m. in an antecubital vein and kept patent with a slow drip of normal saline solution. Blood samples were obtained 30, 45, and 60 minutes after insertion of the intravenous line for determination of baseline hormone concentrations. Immediately after the collection of the last baseline

FIGURE 1. Hormone Responses to Intravenous Administration of Clomipramine in 30 Depressed Patients and 30 Healthy Control Subjects

sample, 100 cc of normal saline containing 12.5 mg of clomipramine were infused over a 15-minute period. Additional blood samples were obtained 30, 45, 60, 90, 120, and 150 minutes after the start of the infusion.

Blood pressure and pulse were measured and recorded at each sampling point throughout the procedure with an automated machine (Criticon, Tampa, Fla.). Visual 100-mm analog scales were used to evaluate six different subjective states (best ever/worst ever, calm/restless, energetic/tired, happy/sad, most/least anxious, and most/least nauseated).

Collection and Assay Techniques

Blood samples were drawn into disposable polypropylene syringes and transferred to heparinized polypropylene tubes (a portion of each sample was placed into EDTA treated glass tubes for ACTH measurement). The samples were immediately placed on ice and promptly centrifuged at 4 °C, and the resultant plasma was stored at -70 °C.

Plasma prolactin and growth hormone concentrations were measured with double antibody radioimmunoassays, which used commercial reagents (Becton Dickinson, Orangeburg, N.Y.; Kallestad Diagnostics, Austin, Tex.). The sensitivities of the prolactin and growth hormone assays were 1.0 ng/ml and 0.2 ng/ml, respectively; the intra-assay and interassay coefficients of variation were 5% and 9% for prolactin and 4% and 7% for growth hormone. Plasma cortisol concentrations were assayed by radioimmunoassay with commercial reagents (Becton Dickinson). The sensitivity of the assay was 0.04 μg/dl, with intra-assay and interassay coefficients of variation of 5% and 7%. Plasma ACTH concentrations were measured by radioimmunoassay with commercial reagents (ICN Biochemicals, Los Angeles). The sensitivity of the assay was 10 pg/ml, and the intra-assay and interassay coefficients of variation were 5% and 7%.

Plasma clomipramine and demethylated clomipramine concentrations were measured by using high per-

formance liquid chromatography with ultraviolet detection, using a modification of a previously described technique (25). Each 0.1 ml-plasma sample was placed in a polypropylene capped conical tube and 50 ng of imipramine (internal standard) in methanol was added, along with 1.0 ml of hexane:isoamyl alcohol (9:1) and 0.01 ml N NaOH. After shaking and centrifuging (5 minutes each), the organic layer was transferred to a clean tube. The organic solution was then evaporated under a stream of nitrogen at ambient temperature, the residue was resuspended with 0.1 ml of mobile phase, and 0.08 ml was injected into the column. The chromatographic system consisted of a silica column (Keystone Scientific, Bellefonte, Pa.), a mobile phase of acetonitrile:methanol:8.5 N ammonium hydroxide (83.3%:16.3%:0.4%) at a gradient flow of 1 to 4 ml/minute, and ultraviolet detection at 214 nm. Twenty to 30 samples were processed simultaneously, including eight to 10 samples to which known amounts of the drugs had been added for construction of a calibration curve. The lower limits of detection were 10 ng/ml for clomipramine and demethylated clomipramine, and the intra-assay and interassay coefficients of variation were between 4% and 10%.

Statistical Analyses

All hormone values were log-transformed to stabilize variances and to approximate normal distributions before the analyses, since the raw hormone values had a strong positive skew; for clarity of presentation, however, raw (i.e., nontransformed) values are presented in figure 1 and in the Results section. The last hormone value before clomipramine infusion was considered to be the baseline value for the purpose of comparison to postinfusion values. Our primary index of hormonal responsivity to clomipramine was defined as the maximum postinfusion change from baseline, or Δ_{max} . Type 1 errors for maximum change were controlled at 5% for each hormone. Because our age match was not exact, we controlled for age in all analyses of maximum change by using one-way analysis of covariance (ANCOVA).

Supplementary analyses used two-way ANCOVA for repeated measures (with age as a covariate), with the Greenhouse-Geisser adjustment for autocorrelation in the data (usually resulting in fractional degrees of freedom). This repeated measures ANCOVA was applied directly to the baseline and the five postinfusion values to assess overall group differences, including any baseline discrepancy between groups. We also applied repeated measures ANCOVA to the five postinfusion changes from baseline to assess the significance of Group by Time interaction in clomipramine responsivity, after controlling for nonsignificant baseline differences. Variables analyzed by repeated measures ANCOVA consisted of the log-transformed values for plasma concentrations of each of the four hormones (prolactin, ACTH, cortisol, and growth hormone), the nontransformed cardiovascular measures

(systolic blood pressure, diastolic blood pressure, and pulse rate), the subjects' response on the six 100 mm-line visual analog scales, and plasma clomipramine concentrations.

Student's *t* test was used to compare mean age and baseline hormone and cardiovascular measures between the groups. Fisher's exact test was used to compare groups with respect to the season during which the clomipramine infusions were given.

These analyses were performed with the Statistical Analysis System software package (26). All *p* values are two-tailed.

RESULTS

The baseline plasma hormone concentrations and cardiovascular measures were not significantly different in depressed patients and control subjects. However, there were trends toward lower levels of prolactin ($t=1.8$, $df=58$, $p<0.08$), ACTH ($t=1.5$, $df=58$, $p<0.16$), and cortisol ($t=1.3$, $df=58$, $p<0.20$) and higher pulse ($t=1.8$, $df=58$, $p<0.09$) in the former group.

The prolactin response to clomipramine was blunted in depressed patients compared to the control subjects. The change in prolactin level was smaller in the former group than in the latter (Δ_{\max} prolactin=2.4 ng/ml, $SD=4.0$, and 7.1, $SD=10.1$; $F=7.7$, $df=1$, 57, $p<0.008$, ANCOVA). ANCOVA confirmed a significant difference in the prolactin response to clomipramine in the depressed patients and control subjects (for Group effect: $F=6.8$, $df=1$, 52, $p<0.02$) (figure 1).

The cortisol and ACTH responses tended to be lower in depressed patients than in control subjects, although these trends did not achieve statistical significance (figure 1). The change in cortisol level was smaller in depressed patients than in healthy subjects (Δ_{\max} cortisol=5.5 μ g/ml, $SD=6.4$, and 9.2, $SD=8.9$; $F=3.8$, $df=1$, 57, $p<0.06$, ANCOVA). Repeated measures ANCOVA revealed a significant Group effect ($F=8.0$, $df=1$, 52, $p<0.007$), reflecting a trend toward a difference at baseline that persisted over time; Group by Time effect did not reach significance ($F=2.0$, $df=2.1$, 111, $p<0.14$). The change in ACTH showed considerable variance within each group, and while the mean value was lower in the depressed group than in the control subjects, the difference was not significant (Δ_{\max} ACTH=27.7 pg/ml, $SD=34.6$, versus 43.9, $SD=75.1$; $F=0.2$, $df=1$, 57, $p>0.63$, ANCOVA). Repeated measures ANCOVA demonstrated a trend toward Group ($F=1.1$, $df=1$, 51, $p<0.31$) and Group by Time ($F=1.4$, $df=2.1$, 111, $p<0.26$) effects, although these trends failed to reach statistical significance.

Depressed patients and control subjects did not demonstrate a substantial difference in growth hormone responses to clomipramine (Δ_{\max} =3.5 ng/ml, $SD=9.1$, and 4.5, $SD=8.5$; $F=0.8$, $df=1$, 57, $p<0.40$, ANCOVA) (figure 1), and repeated measures ANCOVA did not suggest a significant Group effect ($F=0.1$, $df=1$, 53, $p>0.79$).

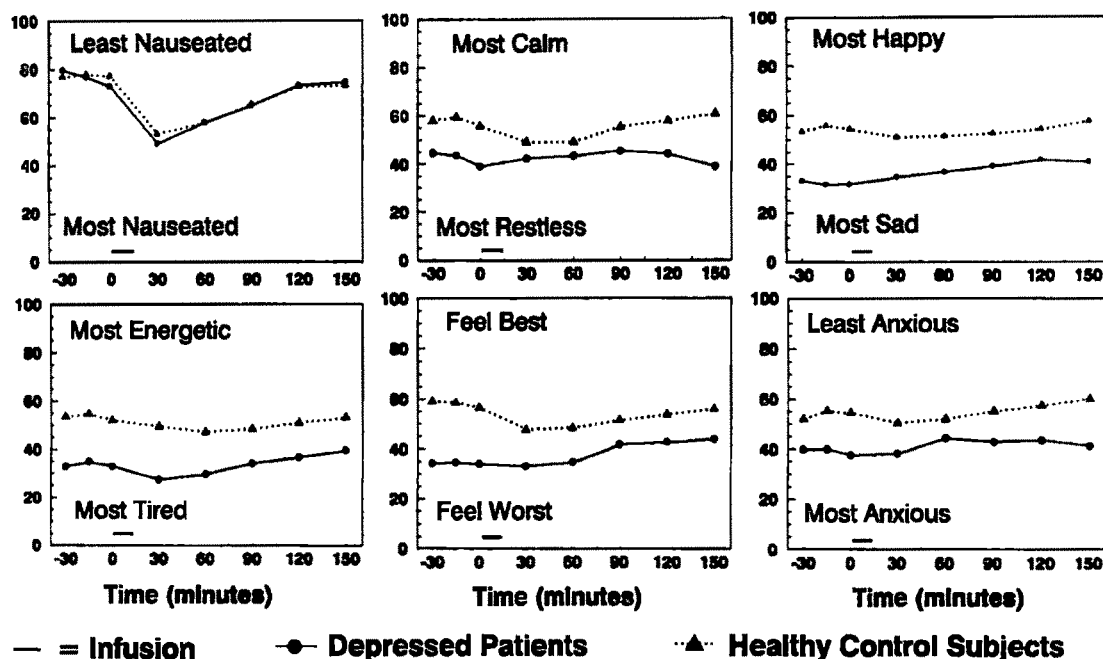

FIGURE 2. Plasma Clomipramine Concentrations in 30 Depressed Patients and 30 Healthy Control Subjects

Plasma clomipramine concentrations were not significantly different in depressed patients and healthy subjects (repeated measures ANCOVA for Group effect: $F=1.1$, $df=1$, 49, $p>0.30$; for Group by Time effect: $F=0.4$, $df=1.5$, 90.5, $p>0.66$) (figure 2). Demethylated clomipramine was not detected in any of the samples.

Both depressed patients and control subjects demonstrated a brief, modest increase in self-reports of nausea after clomipramine infusion, with a return to baseline. There was no significant difference between the groups in terms of nausea self-reports, with minimal Group (repeated measures ANCOVA: $F=0.1$, $df=1$, 57, $p>0.79$) and Group by Time (repeated measures ANCOVA: $F=0.6$, $df=2.6$, 148.0, $p>0.57$) effects. As anticipated, the self-report scores for mood variables were different in patients and control subjects; the former group was more sad and more anxious, felt worse, and was less calm and more tired than the latter (repeated measures ANCOVA Group effects for these self-reports: $F=17.9$, $df=1$, 57, $p=0.0001$; $F=7.7$, $df=1$, 57, $p<0.008$; $F=12.2$, $df=1$, 55, $p<0.001$; $F=5.3$, $df=1$, 5, $p<0.03$; $F=28.4$, $df=1$, 57, $p=0.0001$). There were no significant Group by Time effects in the first three of these mood variables (for sad/happy, least/most anxious, and feeling best ever/feeling worst ever, repeated measures ANCOVA: $F=1.1$, $df=3.1$, 175.3, $p>0.35$; $F=1.6$, $df=2.9$, 162.9, $p>0.19$; $F=1.3$, $df=2.8$, 151.7, $p>0.27$, respectively). There were significant Group by Time effects for most/least calm (repeated measures ANCOVA: $F=4.3$, $df=2.8$, 160.2, $p<0.008$) and feeling most tired/most energetic ($F=2.7$, $df=2.9$, 164.4, $p<0.05$). Depressed patients demonstrated a very modest increase in self-reported calmness and a modest decrease in self-reported tiredness, followed by a return to baseline after clomipramine; control subjects demonstrated a modest decrease in self-reported calmness, followed by a return to baseline, and a very modest, sustained decrease in self-reports of feeling energetic (figure 3). There were no significant group differences in systolic blood pressure, diastolic blood pressure, or pulse after clomipramine infusion (data not shown).

FIGURE 3. Self-Report Scores for Side Effects and Mood States in 30 Depressed Patients and 30 Healthy Control Subjects After Intravenous Administration of Clomipramine

DISCUSSION

The most striking finding to emerge from this study is the blunted prolactin response to intravenous clomipramine in depressed patients. Blunted prolactin responses to various serotonergic probes, including tryptophan (6, 7), fenfluramine (2–5), and now clomipramine, have been observed in depression. While the finding of less prolactin responsivity to serotonergic agents in depressed patients is quite consistent, the interpretation and physiologic bases for these phenomena are not clear. Two important questions need to be considered: Is a given neuroendocrine probe a valid measure of central 5-HT systems? What specific mechanisms are responsible for the abnormal neuroendocrine responses in depressed patients?

Neuropharmacologic probes for 5-HT are predicated on the assumption that the dependent variable, i.e., the hormone that is measured before and after administration of the 5-HT stimulus, is regulated by central 5-HT systems. In fact, the neuroregulation of these anterior pituitary peptides is quite complex; 5-HT plays a role, but so do other neurotransmitters (see reference 27 for a comprehensive review). The goal, therefore, in developing a neuroendocrine probe for 5-HT is to find a challenge agent that affects 5-HT but does not directly affect other neurotransmitters. Even with an ideal, specific 5-HT probe, however, interpretation of results must be tempered by the implications of the multiple neurotransmitter regulation of hormone release. For example, a blunted prolactin response to clomipramine could be related to enhanced tuberoinfundibular dopaminergic activity that 5-HT stimulation is unable to overcome. Arguing against this interpretation is the ob-

servation by Anderson and Cowen (28) that the prolactin response to the dopamine antagonist metoclopramide is not different in depressed patients and control subjects.

All of the currently available 5-HT neuroendocrine probes, including the clomipramine challenge test described in this report, have potential limits regarding their specificity for 5-HT systems. While clomipramine is a fairly potent 5-HT reuptake inhibitor with minimal effects on norepinephrine, its desmethyl metabolite does inhibit norepinephrine uptake (20). In this regard, it is encouraging to note that we were unable to detect demethylated clomipramine in any of our samples, using an assay with a sensitivity of 10 ng/ml. Laakmann's group (29–31) has also found consistent prolactin effects from intravenous clomipramine, although Filip et al. (32) did not in a small study using a lower dose than that employed in the present study.

Like other pro-serotonergic agents, clomipramine administration was associated with nausea, but the amount was mild in our subjects and did not evoke other signs of nonspecific stress (e.g., increased pulse). Perhaps a certain degree of nausea may be inevitable whenever 5-HT stimulation that is sufficient to produce neurohormone release occurs; an emesis center that is partly under 5-HT control may be present in humans. In this study, it is important to note that the self-report ratings of nausea were nearly identical in patients and control subjects, so that nausea per se cannot account for the differences in prolactin release that occurred in the two groups.

The mechanisms responsible for the blunted prolactin responses in depressed patients may differ for the various 5-HT probes (e.g., tryptophan, fenfluramine,

clomipramine). One possible mechanism that has to be considered is a defect in the secretory capacity of anterior pituitary lactotrophs. Some investigators have reported blunted prolactin responses to a variety of challenges, including thyrotropin-releasing hormone (TRH) (33, 34), narcotics (35, 36), and insulin-induced hypoglycemia (37), as well as diminished basal prolactin levels (33, 34) in depressed patients, although the latter finding has not been replicated consistently (38–41). However, we have found that a group of seven depressed patients with blunted prolactin responses to clomipramine were able to mount robust prolactin responses to TRH stimulation (42). Thus, the blunted prolactin response to clomipramine does not appear to be the consequence of diminished lactotroph secretory capacity.

If, in fact, the diminished prolactin response to clomipramine is a reflection of an abnormality in central 5-HT systems, the specific nature of the abnormality remains to be elucidated. Presynaptic alterations may play a role. Delgado et al. (43) have recently demonstrated that acute tryptophan depletion can precipitate the reemergence of depressive symptoms in remitted patients; perhaps similar presynaptic defects could account for some of the neuroendocrine stigmata of depression as well, including the abnormal neurohormone response to clomipramine reported here.

Postsynaptic mechanisms must be considered in the interpretation of these results as well. It is not clear which postsynaptic 5-HT receptor subtype is involved in prolactin regulation. Both 5-HT_{1A} (44) and 5-HT₂ (45–48) receptors have been implicated. Further clarification of the specific mechanisms by which 5-HT affects normal prolactin release might provide important clues regarding the pathophysiologic bases for the abnormal prolactin responses to clomipramine in depression.

The hypothalamic-pituitary axis is also regulated by 5-HT, and we observed trends toward lower ACTH and cortisol responses to clomipramine in depressed patients. The mechanism by which 5-HT affects the hypothalamic-pituitary axis is not clear, although it appears that 5-HT_{1A} receptors play a role (49, 50). As Meltzer has pointed out (51), it is possible that prolactin and cortisol are controlled by separate serotonergic systems that differ in their overall pattern of function. In the rat, there are data that suggest that 5-HT-dependent increases in corticosterone and prolactin are mediated by different neuronal mechanisms (52). Thus, more work is necessary in order to delineate the physiologic bases for our observations.

Our findings of a blunted prolactin response and trends toward blunting in the ACTH and cortisol response to clomipramine are consistent with the results of an earlier pilot study (53), which was conducted at a different site and used a somewhat lower clomipramine dose (i.e., 10 mg). In contrast, however, we detected an exaggerated growth hormone response to clomipramine in that earlier study, yet found no significant abnormality in the growth hormone response to clomipramine in depressed patients in the present investiga-

tion. In our previous study, we noted that the abnormal growth hormone response could be accounted for by extremely robust responses in three of the seven depressed patients. Our speculation regarding erratic growth hormone release in depression, perhaps as a consequence of noradrenergic dysregulation, remains the most conservative explanation of that earlier finding, which failed to reemerge in this larger, more controlled study.

Recently, Jarrett et al. (54) reported finding no difference in sleep-related prolactin responses to intravenous clomipramine in depressed outpatients and healthy subjects. Several important methodological differences may have contributed to this apparent discrepancy between their findings and our results. First, as Jarrett et al. point out, the hormonal response pattern to a provocative stimulus will vary during the day, and for many hormones, there is a diurnal sensitivity to pharmacologic stimuli consistent with differences in neurotransmitter tone over the course of the day. Second, the experimental (depressed) and control subjects in the Jarrett et al. study were not matched for age or sex. For example, the control group was significantly younger than the patient group (30.3 versus 42.4 years; $p=0.01$). Since we have found that younger healthy subjects have significantly lower prolactin responses to clomipramine than older healthy subjects (55), the younger age of Jarrett et al.'s control group could account for the lack of observed blunting in the depressed group. Finally, the sample size in the Jarrett et al. study was so small (eight depressed patients and five healthy control subjects) that their power to detect a difference between groups comparable to the difference we report here (i.e., standardized effect size, $d=0.74$) was only 20%.

Given the complexity of the neurochemical systems that regulate pituitary hormone release, the precise mechanisms responsible for the abnormal neuroendocrine profile seen in depressed patients after clomipramine challenge are not yet defined. We believe that these findings are related to dysregulation of central serotonergic systems in depression. However, additional investigations will be necessary to test this hypothesis and to clarify further the nature of such dysregulation.

Prevalence of Seasonal Affective Disorder in Alaska

John M. Booker, Ph.D., and Carla J. Hellekson, M.D.

Objective: The goals of this study are to provide estimates of the prevalence of seasonal affective disorder in Alaska, to examine sociodemographic correlates, and to evaluate the relation between seasonal affective disorder and general depression. **Method:** A random sample of 283 residents of Fairbanks who had lived in Alaska for 3 years or more were interviewed with the Seasonal Pattern Assessment Questionnaire and the Center for Epidemiologic Studies Depression Scale (CES-D Scale). **Results:** Twenty-six (9.2%) of the subjects met diagnostic criteria for seasonal affective disorder, one of the highest figures yet reported. These cyclic winter affective disorders occurred more often in women than men (ratio=3:2) and were less prevalent among residents who were older than 40 years of age. Assessment of depression with the CES-D Scale supported the diagnostic classification of respondents and the differentiation of seasonal affective disorder from other depression. **Conclusions:** This study supports the conclusions that seasonal affective disorder is prevalent in northern populations and that sex and age may represent the major risk factors that differentiate it from the general experience of depression in northern communities.

(Am J Psychiatry 1992; 149:1176-1182)

The darkness, cold, and isolation then drive the mental faculties on to melancholy . . . The earliest effects become manifest in the mental realm. The physical changes become evident slowly, often not at all until near the end or at sunrise of the next year.

—Dr. Frederick Cook, circa 1897 (1, pp. 113, 115)

Seasonal changes in mood and energy have long been accepted as a feature of life in the far north, and Dr. Cook was one of the early medical observers who described such effects. With the introduction of the diagnosis of seasonal affective disorder (2, 3), questions about the incidence and prevalence of seasonal mental health problems have been raised. This study provides estimates of the prevalence of seasonal affective disorder in Alaska, examines sociodemographic correlates, and evaluates the relation between seasonal affective disorder and general depression.

BACKGROUND

Seasonal affective disorder (major depression, seasonal pattern, in *DSM-III-R*) has been characterized by

onset during autumn of depressive symptoms with an atypical pattern, featuring hypersomnia, irritability, weight gain, and carbohydrate craving. Among clinical populations the syndrome is more common in women, in a ratio of about 4:1 (4), which is higher than the 2:1 ratio noted in depressive illness in general (5). Clinical histories of patients receiving phototherapy for seasonal affective disorder suggest that depressive episodes last longer the farther north the patients live (4).

In a random mail survey of 400 New York City residents (6), seasonal symptoms were common among the 193 respondents. Wintertime fatigue was reported by 50%, winter weight gain by 47%, increased sleep by 42%, and decreased social activity by 31%; 31% of the respondents said they felt worse in the winter.

Among the 383 subjects who responded to a telephone survey of 416 randomly chosen residents of Montgomery County, Md. (7), seasonal affective disorder was estimated at 4.3% (71% female) and subsyndromal seasonal affective disorder (milder complaints) at 13.5% (55% female). Clinical interviews with a 10% subsample of the respondents revealed that the designations of no seasonal affective disorder, subsyndromal seasonal affective disorder, and seasonal affective disorder were consistent with levels of depression measured with the Hamilton Rating Scale for Depression (8, 9).

A random mail survey of 1,576 residents at four different latitudes in the United States (10) produced estimates for seasonal affective disorder ranging from 1.4% in Sarasota, Fla., to 9.7% in Nashua, N.H. Response rates for the four sites ranged from 40.1% to 60.5%.

Received Sept. 8, 1989; revision received Dec. 30, 1991; accepted Jan. 24, 1992. From the School of Nursing and Health Sciences, University of Alaska Anchorage. Address reprint requests to Dr. Hellekson, Eastside Group Health, 2700 152nd St., N.E., Redmond, WA 98052.

Clinical studies of seasonal affective disorder in Alaska have been completed, but no epidemiologic data have been available (4, 11). Fairbanks lies at a latitude of 64° north, presenting an environment of extreme seasonal contrasts. Available daylight at winter solstice is approximately 3 hours and 42 minutes, but at summer solstice the available daylight is 21 hours and 49 minutes. This provides opportune conditions under which to assess the relation between extreme seasonal changes and depression.

METHOD

Subjects

This study of the prevalence of seasonal affective disorder was part of a larger community health survey based on standardized household interviews administered from mid-January through mid-March to a multistage area probability sample of 283 adult (21 years or older) residents of Fairbanks, Alaska (total population=75,000). Potential subjects who were living on military bases, on university campuses, or within hospitals, nursing homes, etc., were not included. In addition, only those respondents who had lived in Alaska for 3 years or more were included to ensure sufficient exposure to the seasons there to establish a repeated seasonal pattern of related symptoms. The 283 subjects who participated in the interviews represented 91% of all respondents interviewed after two calls back (N=310). (The 310 subjects interviewed represented a response rate of 86% of the original 360 household contacts.)

The Measurement of Seasonal Affective Disorder

Population estimates of seasonal affective disorder were based on the Seasonal Pattern Assessment Questionnaire developed at the National Institute of Mental Health (12, 13). Follow-up clinical interviews and independent measures of depression have provided initial validation of the use of the Seasonal Pattern Assessment Questionnaire in epidemiologic studies (10). Furthermore, prevalence estimates based on the Seasonal Pattern Assessment Questionnaire show the expected variation by latitude (6, 7, 10).

The global seasonality score used in this study was derived from six questions on the Seasonal Pattern Assessment Questionnaire regarding changes in mood (overall feeling of well-being), sleep length, social activity, weight, appetite, and energy level. Each of these items was rated on a 5-point scale on which 0=no change and 4=extremely marked change. The potential range of scores was 0 to 24. Global seasonality scores were linked with an assessment of the severity of complaints of the combined symptoms on a 5-point scale on which 1=mild and 4=disabling. These two items were used to group respondents into those with seasonal affective disorder, those with subsyndromal seasonal af-

fective disorder, and those with no seasonal affective disorder (normal subjects).

Differing threshold values for global seasonality score have been used; a global seasonality score of 10 or more has been applied in some telephone surveys, but a global seasonality score of 11 or more has been used in self-administered surveys (7). We chose the higher threshold value for our analyses, thus potentially underestimating the prevalence of seasonal affective disorder. However, prevalence estimates based on both criteria will be compared.

Measurement of General Depression

General depression was measured with the 20-item Center for Epidemiologic Studies Depression Scale (CES-D Scale) (14). This scale assesses the presence and frequency of depressive symptoms over the previous week. The CES-D Scale has been used effectively in cross-ethnic studies (15), and its validity has been demonstrated with rural populations (16). The self-administered CES-D Scale has been shown to correlate moderately well with the Hamilton Rating Scale for Depression (14).

RESULTS

Prevalence of Seasonal Affective Disorder

Table 1 reviews the criteria and resulting assignment of the subjects to diagnostic groups. Estimates based on the higher threshold (used in the self-administered tests) and the lower threshold (used in telephone surveys) are presented. Subsequent analysis will be based on groups defined by the higher global seasonality score.

As shown in table 1, 9% of the Fairbanks respondents met criteria for seasonal affective disorder and another 19% met criteria for subsyndromal seasonal affective disorder. A chi-square test of hypothesized proportions for the two classification schemes was not significant (table 1), indicating that the estimates for the two global seasonality score criteria were within the limits of random variation. The higher rates according to the lower global seasonality score value came from the category of subsyndromal seasonal affective disorder (table 1).

Individual Characteristics

Univariate comparisons of the sociodemographic characteristics of the subjects in the three diagnostic groups are given in table 2. The proportion of women in each group, although lower than that reported for clinical populations, was significantly higher in the groups of subjects with seasonal affective disorder and subsyndromal seasonal affective disorder than in the group of normal subjects.

No statistically significant differences were found for ethnicity; the prevalence of seasonal affective disorder

TABLE 1. Prevalence of Seasonal Affective Disorder in 283 Residents of Fairbanks, Alaska, According to Two Diagnostic Thresholds

Threshold ^a	Seasonal Affective Disorder			Subsyndromal Seasonal Affective Disorder			No Seasonal Affective Disorder		
	Criteria ^b	N	%	Criteria ^b	N	%	Criteria ^b	N	%
Higher threshold	Global seasonality score ≥ 11 and complaints rated ≥ 2	26	9.2	Global seasonality score ≥ 11 and complaints rated 0 or 1 or global seasonality score = 9 or 10 and complaints rated 1	54	19.1	Global severity score < 9 or global severity score = 9 or 10	203	71.7
Lower threshold	Global seasonality score ≥ 10 and complaints rated ≥ 2	28	9.9	Global seasonality score ≥ 10 and complaints rated 1 or global seasonality score = 8 or 9 and complaints rated 2	68	24.0	Global seasonality score < 8 or global seasonality score = 8 or 9 and complaints rated 1	187	66.1

^aDifferences in diagnostic assignment of patients by the two thresholds were not statistically significant ($\chi^2=5.04$, $df=2$, n.s.).

^bThe global seasonality score was derived from six questions rating sleep length, social activity, weight, appetite, and energy level on a 5-point scale on which 0=no change and 4=extremely marked change. The potential range of scores was 0 to 24. The severity of the respondent's complaints of the combined symptoms was rated a 5-point scale on which 1=mild, 2=moderate, 3=marked, 4=severe, and 5=disabling.

TABLE 2: Relation of Sociodemographic Characteristics to Seasonal Affective Disorder in 283 Residents of Fairbanks, Alaska^a

Characteristic	Subjects With Seasonal Affective Disorder (N=26)		Subjects With Subsyndromal Affective Disorder (N=54)		Normal Subjects (N=203)		Total (N=283)		χ^2 (df=2)	p
	N	%	N	%	N	%	N	%

was not demonstrated to differ among white, black, and Alaska Native respondents. Caution must be applied in interpreting this finding because the sizes of the nonwhite groups are small. Differences in education level, employment status, and marital status were not significant.

Consistent with earlier studies (7, 10), there was a significant difference in mean age among the three groups: the group with subsyndromal seasonal affective disorder was youngest and the group without seasonal affective disorder was the oldest. The mean age of the

subjects with seasonal affective disorder was 35.81 years ($SD=11.87$), and that of the subjects with subsyndromal seasonal affective disorder was 34.78 ($SD=9.92$). These two groups were about 6 years younger than the normal subjects, whose mean age was 42.02 ($SD=13.57$) ($F=8.41$, $df=2$, 280 , $p<0.05$).

The mean length of time the subjects had lived in Alaska also varied significantly. The subjects with seasonal affective disorder had been in Alaska for a mean of 14.81 years ($SD=8.61$), the subjects with subsyndromal seasonal affective disorder had been there for 11.96

years (SD=6.25), and the normal subjects had been there for 17.6 years (SD=11.15) ($F=6.72$, $df=2$, 280, $p<0.05$). Age and time spent in Alaska, as might be expected, were correlated ($r=0.51$, $df=282$, $p<0.01$).

Multivariate Analysis

To further investigate the observed associations between these potential predictor variables and seasonal affective disorder, a multivariate logistic regression analysis was applied to the variables involved. In addition to sex, age, and amount of time the subject had lived in Alaska, ethnicity was included in the analysis because of potential theoretical interest.

Because the subjects were classified into three diagnostic groups, polytomous logistic regression techniques were used (17). This approach yields two sets of parameters for the logits involving two comparisons of dependent variable categories. The first logit compared normal subjects and subjects with seasonal affective disorder; the second compared normal subjects and subjects with subsyndromal seasonal affective disorder. Interpretation of each set of parameter estimates and their tests of significance is the same as that for a conventional logistic regression using a dichotomous dependent variable. This approach provides estimates based on the differences among the diagnostic categories within a single analysis.

The independent variables were treated as dichotomies. Dichotomous predictor variables were used to facilitate interpretation of odds ratios (the relative odds of being in a particular diagnostic group for subjects in one predictor category compared with subjects in the other category of the same predictor variable). Treating age and the number of years the subject had lived in Alaska as continuous variables produced no substantial differences in the results of the analysis.

Table 3 shows the logistic coefficients, standard errors, and odds ratios for the four independent variables in each binary combination of categories of the depend-

ent variable. For each comparison, one value of the independent variable serves as the reference category for the other value. Only main effects are shown because no significant interactions among independent variables were detected.

In the comparison of subjects with seasonal affective disorder versus normal subjects, we found that women were 2.96 times more likely than men to be in the seasonal affective disorder group. Those under 40 years of age were 2.84 times more likely to be in the seasonal affective disorder group. The number of years the subject had lived in Alaska was not significant in this multivariate analysis, a function of its correlation with age. The univariate relation in table 2 may be considered misleading. Ethnicity does not discriminate between general depression and seasonal affective disorder.

The comparison of subjects with subsyndromal seasonal affective disorder versus normal subjects showed essentially the same pattern as the comparison of subjects with seasonal affective disorder versus normal subjects (table 3). Women were 1.98 times more likely to be in the seasonal affective disorder group, and younger subjects were 3.88 times as likely to be classified as having subsyndromal seasonal affective disorder. The effect of number of years the subjects had lived in Alaska approached significance in this comparison. Further research should examine the potential relation between subsyndromal seasonal affective disorder and length of time in a northern environment.

Further analysis comparing the subjects with seasonal affective disorder and those with subsyndromal seasonal affective disorder revealed no statistically significant differences on these sociodemographic variables. Sex and age effects were statistically equivalent for these two groups.

General Depression and Seasonal Affective Disorder

The subjects reporting symptoms consistent with a clinical diagnosis of seasonal affective disorder had a

mean CES-D Scale score of 15.08 (SD=9.75), those with subsyndromal symptoms of seasonal affective disorder had a mean score of 11.19 (SD=10.33), the normal subjects had a mean score of 6.01 (SD=6.91), and the whole group had a mean score of 7.84 (SD=8.50). The one-way analysis of variance, conducted to examine between-group differences on mean scores, indicated that the subjects reporting symptoms consistent with a clinical diagnosis of seasonal affective disorder and those with subsyndromal symptoms of seasonal affective disorder had significantly higher scores than normal subjects and the group as a whole ($F=20.22$, $df=2$, 270, $p<0.0000$) ($R=0.36$, $df=282$, $R^2=0.13$). The pattern of scores and the strength of the group differences support the assignment of members to groups according to the Seasonal Pattern Assessment Questionnaire diagnostic criteria.

The mean CES-D Scale score for the entire sample was near the lower end of the range of other reported population means, typically 8.0 to 9.3 (14). Average levels of general depression in Fairbanks during the winter are comparable to those in other communities in the United States. Although the CES-D Scale is not generally used as a diagnostic tool, scores of 16 or more may indicate clinical depression (14, 18).

Diagnoses of seasonal affective disorder and subsyndromal seasonal affective disorder have been shown to be related to sex, age, and general depression classified according to the CES-D Scale, but the question remains as to how seasonal affective disorder differs from general depression. Although the available data do not allow a definitive test of this question, we conducted an assessment of whether the risk factors of sex and age have a unique relationship to seasonal affective disorder or are related only through more general underlying depression.

Table 4 shows the results when CES-D Scale depression scores were added to the logistic regression model

developed in table 3. CES-D Scale depression scores were entered as a continuous variable, serving as a covariate or control variable, and the resulting parameters were estimated simultaneously.

In the comparison of subjects with seasonal affective disorder versus normal subjects the only notable change was that there was no longer a significant difference in the ages of the two groups with depression held constant, although the subjects with seasonal affective disorder still tended to be younger. The comparison of subjects with subsyndromal seasonal affective disorder and normal subjects did not change in any significant way. The probability for the number of years the subject had lived in Alaska parameter approached significance ($p<0.05$). This relation should receive further attention in future research. After controlling for differences in depression, subjects with seasonal affective disorder or subsyndromal seasonal affective disorder were more likely to be women and subjects with subsyndromal seasonal affective disorder were likely to be younger.

For both comparisons, subjects with seasonal affective disorder and subsyndromal seasonal affective disorder had significantly higher general depression scores, regardless of sex or age. An odds ratio for each unit of increase in general depression (here 5 points was chosen) showed the increasing likelihood that a subject would be in the seasonal affective disorder or subsyndromal seasonal affective disorder group (table 4). This estimate assumed that the relation between seasonality and affective disorder is linear; exact estimates should be interpreted with caution.

A more global interpretation of these findings is that when general depression is controlled for, age and sex are still related to seasonal affective disorder. Among women and men with the same levels of general depression, women were more likely to be diagnosed with seasonal affective disorder, and younger people were more

at risk than older people with the same level of general depression. Further, the pattern of general depression across groups remained and was not the result of age and sex differences among respondents. Seasonal affective disorder and general depression measured by the CES-D Scale are related, but the fact that sex and age differences remained suggests that seasonal affective disorder may represent a domain somewhat distinct from depressive symptoms *per se*.

DISCUSSION

These findings indicate that more than one in four residents of Fairbanks, Alaska, may be adversely affected by the dramatic seasonal changes occurring at that latitude. Nearly one in 10 suffers symptoms severe enough to be given a diagnosis of seasonal affective disorder.

Table 5 summarizes prevalence estimates from this and comparable studies (6, 7, 10) using random sampling and measures of seasonal affective disorder based on the Seasonal Pattern Assessment Questionnaire. The estimates for seasonal affective disorder and subsyndromal seasonal affective disorder are ordered by the latitude at which the study took place. The estimated prevalence of seasonal affective disorder for Fairbanks was higher than estimates for all areas reported except Nashua, N.H. However, when a global seasonality score value of 10 rather than 11 was used to define seasonal affective disorder, the prevalence estimate for Fairbanks became 9.9% (table 1), surpassing Nashua. Fairbanks had the highest figure for subsyndromal seasonal affective disorder and for the combination of seasonal affective disorder and/or subsyndromal seasonal affective disorder. These seven studies generally support the widely held hypothesis that the prevalence of seasonal affective disorder increases with latitude and the corresponding extreme seasonal shifts in available daylight. Therefore, phototherapy, a unique treatment for seasonal affective disorder, may have widespread clinical application during the winter season in the far north.

In the current study, only age and sex were demonstrated to be associated with the occurrence of seasonal affective disorder (table 3). Younger people of both sexes were more likely to have seasonal depressive symptoms and were more likely to be diagnosed with

seasonal affective disorder. Both older and younger women were more likely to experience seasonal affective disorder. These risk factors remained significant when differences in general depression were controlled for (table 4). These findings in a community population are similar to those for clinical populations in which early onset and a high predominance of women have been found (3).

General depression was associated with seasonal affective disorder in this study. The subjects with seasonal affective disorder had significantly higher CES-D Scale scores than normal subjects and subjects with subsyndromal seasonal affective disorder, and subjects with subsyndromal seasonal affective disorder had significantly higher CES-D Scale scores than normal subjects. The relation between general depression and seasonal affective disorder persisted, even when age and sex differences were controlled for (table 4). The Seasonal Pattern Assessment Questionnaire appears to be sensitive to general depression while differentiating seasonal affective disorder on the basis of age and sex.

The small number of Alaska Natives limits the opportunity to test for the potential effects of differences in race/ethnicity, especially between Alaska Natives and non-Alaska-Natives. Moreover, all Alaska Natives in this sample were residing in an urban environment, preventing the exploration of potential mediating influences of differences in life style. Adaptation to a northern environment remains an important issue for future studies.

This study supports the conclusions that seasonal affective disorder is a depressive disorder that is prevalent in northern populations and that sex and age may represent the major risk factors that differentiate it from the general experience of depression in those communities. Further research to define populations at risk and to identify factors associated with treatment outcome may improve the well-being and productivity of those affected by seasonal affective disorder and its subsyndromal manifestations.

Duration of Psychosis and Outcome in First-Episode Schizophrenia

Antony D. Loebel, M.D., Jeffrey A. Lieberman, M.D., Jose M.J. Alvir, D.P.H., David I. Mayerhoff, M.D., Stephen H. Geisler, M.D., and Sally R. Szymanski, D.O.

Objective: This study was undertaken to assess the potential effect of duration of untreated illness on outcome in a group of first-episode schizophrenic patients. **Method:** Seventy patients with schizophrenia diagnosed according to the Research Diagnostic Criteria entered the study and were followed for up to 3 years. All patients received standardized treatment and uniform assessments both during the acute phase of their illness and throughout the follow-up period. Outcome was measured in terms of time to remission of acute psychotic symptoms as well as degree of symptom remission. **Results:** The mean duration of psychotic symptoms before initial treatment was 52 weeks, preceded by a substantial prepsychotic period. According to survival analysis, duration of illness before treatment was found to be significantly associated with time to remission as well as with level of remission. The effect of duration of illness on outcome remained significant when diagnosis and gender variables, themselves associated with outcome, were controlled in a regression analysis. Duration of illness was not correlated with age at onset, mode of onset, premorbid adjustment, or severity of illness at entry into the study. **Conclusions:** Duration of psychosis before treatment may be an important predictor of outcome in first-episode schizophrenia. Acute psychotic symptoms could reflect an active morbid process which, if not ameliorated by neuroleptic drug treatment, may result in lasting morbidity. Further implications of these findings are discussed.

(Am J Psychiatry 1992; 149:1183-1188)

Considerable attention has been focused on clinical factors that may influence the outcome of patients with schizophrenia. These have included premorbid factors such as the patient's level of social and educational functioning, age at onset of illness, mode of onset of illness, diagnosis, and gender. Poor premorbid adjustment, early and gradual mode of onset, the absence of affective features, and male gender have all been associated with poorer outcome. These findings have contributed to the notion that factors inherent in a patient's illness determine outcome (1).

At the same time, several investigators have described

the potential impact on outcome of duration of untreated illness, i.e., the time interval between symptom onset and institution of neuroleptic treatment (2-9). Crow et al. (2) reported that among 120 patients in their first episode of schizophrenia who were followed for 2 years in a randomized, placebo-controlled trial of maintenance neuroleptic treatment, relapse subsequent to initial hospital discharge was substantially more common in those whose pretreatment illness lasted more than 1 year. Relapse rates in this group were high: only 18% of the patients who were given active treatment and none who were given placebo remained free of relapse after 2 years. May et al. (3-5) randomly assigned 228 first-admission schizophrenic patients to five treatment groups, three of which did not include drug treatment (psychotherapy, milieu therapy, and ECT groups) and two of which did (drug alone and drug plus psychotherapy). Patients from the first three groups who did not respond were subsequently treated with antipsychotic drugs. In this investigation the drug-treated groups showed the best response and, together with the ECT group, showed the best outcome for up to 3 years (as measured by clinical, social, and psychological test criteria). Thus, the groups initially not treated with medication were found to have a poorer

Copyright © 1992 American Psychiatric Association.

outcome over the follow-up period, despite the fact that subsequent treatment after the index admission was similar (although not standardized) among all groups. Wyatt (6, 7) has recently shown, in a new analysis of these data, that following discharge, patients who had not been treated with neuroleptics and who were discharged within 6 months of initial hospitalization required significantly more rehospitalization and as much subsequent neuroleptic treatment as patients who had initially received neuroleptics. Thus, even patients who initially responded well to nonneuroleptic treatment subsequently fared worse than patients who were initially treated with neuroleptics.

Further evidence for the finding that early neuroleptic treatment can enhance treatment response and outcome in schizophrenia may be derived from early studies on antipsychotic drug use (6, 8). Angrist and Schulz (8) reviewed 10 of these investigations (performed in the 1950s) that studied both acute and chronic patients who had not previously received drug treatment. Poorer response to neuroleptics was found among the chronic patients in six studies, suggesting that delay in drug treatment may lead to a significantly worse outcome.

Lo and Lo (9), in a retrospective 10-year follow-up study of 133 Chinese schizophrenic patients aged 14 to 60 years, found that shorter duration of untreated illness prior to the initial acute episode was significantly associated with favorable outcome ($p < 0.01$). Inoue et al. (10), in a retrospective evaluation of 19 treated adolescent schizophrenic and schizophreniform patients, noted that the time interval between onset of illness and first outpatient treatment varied from 1 to 6 years. Less favorable outcome—specifically, poor occupational or scholastic achievement at 3-year follow-up—was predicted by longer duration of illness (4 years or more). Rabiner et al. (11) studied a group of 64 first-episode subjects with varied diagnoses and found that the 36 schizophrenic patients had a mean duration of illness (from first signs of behavioral changes to baseline interview) of 14.5 months. This study also found that the longer the duration of illness, the poorer the outcome, as measured by presence (or absence) of remission or relapse over a 1-year follow-up period.

The question of whether the duration of psychotic symptoms prior to treatment affects the subsequent course and outcome of schizophrenia has important implications for the nature of both schizophrenic pathophysiology and treatment strategies. Previous studies have generally been retrospective, have involved diagnostically heterogeneous patient groups, and/or have not standardized both acute and maintenance treatment and follow-up. To explore the prognostic significance of the duration of acute symptoms prior to treatment, we examined the relation between outcome and various clinical factors, including premorbid adjustment, age at onset, mode of onset, diagnosis, gender, and duration of illness prior to treatment, in a group of first-episode psychotic patients. Patients were followed for up to 3 years with the use of a standardized treatment protocol and follow-up assessments.

METHOD

Subjects in this study were drawn from a larger, ongoing prospective study of psychobiology in first-episode schizophrenia, the design and procedures of which have been previously described (12). In summary, the subjects were hospital inpatients, all of whom were in the acute phase of their first psychotic episode, necessitating hospital admission, who met the Research Diagnostic Criteria (RDC) (13) for schizophrenia or schizoaffective disorder, mainly schizophrenic. The subjects had not received more than 12 weeks of neuroleptic treatment in their lifetime; 70% of the group had never received any neuroleptic. If patients had received medications before admission, these were withdrawn at least 14 days before the baseline evaluations. No subject had a past history of significant neurological or endocrine disorder or persistent or severe substance abuse. All patients, as well as their families, were advised of the study and gave written informed consent.

Psychopathology at baseline was evaluated with the following measures: the Schedule for Affective Disorders and Schizophrenia (SADS) (14), the Scale for the Assessment of Negative Symptoms (15), and the Clinical Global Impression (CGI) scale (16). During their initial hospital admission, patients' premorbid status was investigated with the Premorbid Adjustment Scale (17), and age at onset and mode of onset of illness were ascertained by interviews with the patients and family members. Multiple informants were available and were used to obtain these data for all study subjects. Onset of illness was determined in two ways. First, we asked patients and their family members when the patient (or the family member) first experienced (or noticed) behavioral changes which, in retrospect, appear to have been related to the patient's becoming ill. Second, after explaining psychosis in clear language, we asked when the patient (or the family member) first experienced (or noticed) psychotic symptoms. When differences between patients' and family members' responses occurred, a consensus decision was made by the research staff. All of these evaluations were made by staff members who were blind to patients' treatment response and outcome.

After completion of baseline procedures, patients received open standardized treatment following the study treatment algorithm (12). This consisted of an initial trial of fluphenazine, 20 mg/day p.o., for 6 weeks. If patients were clinically nonresponsive (as determined by lack of significant improvement in positive symptoms and/or presence of residual psychotic symptoms), the fluphenazine dose was increased to 40 mg/day p.o. for 4 weeks. At this point, clinical nonresponders received a 6-week trial of haloperidol, 20 mg/day p.o., followed by an increase to 40 mg/day p.o. for a further 4 weeks, as indicated. Patients with continuing poor clinical response were then given a third neuroleptic trial with a drug from a different biochemical class (molindone), for up to 6 weeks, in moderate to high dose ranges. Adjunctive treatment with lithium was given at

the end of either the haloperidol or the molindone trial. Finally, treatment-resistant patients were considered for clozapine treatment. Patients who relapsed subsequent to initial hospitalization were treated with the same medication and dose to which they had first responded. If necessary, depending on clinical response, they then received further treatment according to the treatment algorithm.

Patients were evaluated biweekly during acute treatment and monthly during the maintenance phase on the SADS (Change Version; SADS-C) with added items from a Psychosis and Disorganization Scale, the Scale for the Assessment of Negative Symptoms, and the CGI. Remission was defined as ratings of 3 or lower on the SADS-C and Psychosis and Disorganization Scale psychosis items, a CGI severity item rating of mild or less, and a rating of at least much improved on the CGI improvement item. Furthermore, this level of response was required to persist for at least 8 weeks (four consecutive biweekly ratings).

Statistical analysis included chi-square tests with Yates' correction for categorical data and Student's *t* tests for continuous data. Pearson's correlation coefficients were calculated to assess the effects of pretreatment variables on degree of remission. Survival analysis according to the Cox proportional hazards model (18) was used to test for effects of diagnosis, gender, and duration of illness on outcome. The Cox model allows for a more sensitive measure of outcome than simply presence or absence of treatment response by focusing on the time to remission (or treatment status at study endpoint). This model also enables consideration of the impact of several simultaneously entered variables on time to treatment response.

RESULTS

Analyses were performed on the data of 70 patients who met the inclusion criteria and were followed for a minimum of 8 weeks in the study. Fifty-six percent (*N*=39) of the patients were male. The mean age at entry into the study was 24.3 years (*SD*=6.0). Seventy-seven percent (*N*=54) of the patients met the RDC for schizophrenia and 23% (*N*=16) for schizoaffective disorder. Of the 70 study subjects, 44% were Caucasian, 32% were black, 17% were Hispanic, and 7% were Asian. According to Hollingshead and Redlich's Two-Factor Index of Social Position (19), 10% were from class I (upper), 19% from class II (upper middle), 28% from class III (middle), 13% from class IV (lower middle), and 28% from class V (lower). Nineteen percent of the group were high school graduates only, and 61% had at least some college education. Eighty percent of the group had never married, 10% were married, and 10% were separated or divorced. All of the patients were actively psychotic, with ratings of at least 4 on one or more of the SADS-C and Psychosis and Disorganization Scale psychosis items and at least 4 (moderately ill) on the CGI severity item.

The mean age at onset of psychotic symptoms was 23.3 years (*SD*=5.9). Duration of illness was defined in two ways: the time interval from onset of unusual behavioral or prodromal (psychiatric) symptoms to study entry and from onset of psychotic symptoms to study entry. The mean duration of illness from the onset of psychiatric symptoms was 150.8 weeks (*SD*=176.6), and the duration from the onset of psychotic symptoms was 51.9 weeks (*SD*=82.3). Duration of illness before treatment was not significantly different for the schizophrenic and schizoaffective subjects: the mean duration since onset of psychiatric symptoms was 155.1 weeks (*SD*=170.3) for the schizophrenic patients and 136.6 weeks (*SD*=201.3) for the schizoaffective patients; the mean duration since the onset of psychotic symptoms was 56.6 weeks (*SD*=89.0) for the schizophrenic patients and 35.9 weeks (*SD*=53.2) for the schizoaffective patients. Duration of psychotic symptoms for male subjects (mean=69.7 weeks, *SD*=104.3) was significantly longer than for female subjects (mean=29.4 weeks, *SD*=29.2) (*t*=2.3, *df*=45, *p*<0.03). Mode of onset was defined in terms of the time interval between the onset of psychiatric (prodromal) symptoms and the onset of psychotic symptoms. This time interval lasted a mean of 98.5 weeks (*SD*=156.6) for the whole study group. The mode-of-onset time interval was not significantly different for the schizophrenic and schizoaffective subjects, nor was there a gender difference. Male subjects were consistently younger at the onset of psychotic symptoms (mean age=22.4 years, *SD*=5.9, versus 24.3 years, *SD*=5.9, for the females) and at entry into the study (mean=23.8 years, *SD*=6.1, versus 24.9 years, *SD*=5.9, for the females). They also had a longer duration of illness since onset of any prodromal symptoms (mean=165.5 weeks, *SD*=155.6, versus 131.7 weeks, *SD*=201.8, for the females). However, these gender differences were not statistically significant.

According to the Cox proportional hazards model of survival analysis, duration of illness from onset of psychotic symptoms was a significant predictor of time to treatment response ($\chi^2=4.52$, *df*=1, *p*<0.03), with longer pretreatment symptom duration being associated with longer time to remission (table 1). This relationship was only slightly affected by a logarithmic transformation of the illness duration variable, indicating that the effect of outliers (patients with extremely long illness) on this finding was minimal. There was a trend for duration of psychotic symptoms to be associated with diagnosis as well as with gender. To control for diagnosis and gender, an analysis was done in which diagnosis, gender, and duration of illness were entered simultaneously into the Cox regression model. Duration of psychotic symptoms before treatment remained significantly associated with time to remission ($\chi^2=4.38$, *df*=1, *p*<0.04), whereas diagnosis and gender did not. Mode of onset was not associated with time to remission.

To examine the relation of pretreatment variables to outcome in another way, patients were classified (at the endpoints of their participation in the study) as in full

TABLE 1. Results of Individual Cox Regression Analyses for Associations Between Pretreatment Variables and Time to Remission in 70 First-Episode Schizophrenic Patients

Pretreatment Variable	Cox Regression Coefficient ^a	Analysis	
		χ^2 (df=1)	p
Duration of psychotic symptoms	-0.005	4.52	0.03
Duration of psychiatric (prodromal) symptoms	-0.0014	2.24	0.13
Mode of onset ^b	-0.0003	0.10	0.76
Age at onset of psychotic symptoms	0.026	1.70	0.19
Age at study entry	0.013	0.42	0.52
Premorbid adjustment			
Childhood	-0.12	0.72	0.40
Early adolescence	-0.24	2.23	0.14
Late adolescence	-0.17	2.24	0.13
Adulthood	0.09	0.63	0.43

^aEstimates the increase in "risk" of remission for each unit increase in the pretreatment variable.

^bInterval between onset of prodromal symptoms and onset of psychotic symptoms.

remission (complete response to treatment with no residual symptoms; 74%, N=49), partial remission (substantial improvement in positive symptoms but with some remaining residual positive or negative symptoms; 12%, N=8), and no remission (continued active positive symptoms; 14%, N=9) after the initial episode. Duration of illness since onset of psychiatric (prodromal) symptoms and duration of illness since onset of psychotic symptoms were correlated significantly with this measure of outcome (table 2). The mode-of-onset variable was not significantly associated with level of remission.

Earlier age at onset of psychotic symptoms was not significantly related to time to remission but was significantly associated with level of remission ($r=-0.25$, $df=64$, $p<0.05$), with younger age predicting poorer outcome. To determine whether premorbid differences among patients accounted for any variation in illness duration and outcome, premorbid adjustment (according to the Premorbid Adjustment Scale) was determined during childhood, early adolescence (ages 12–15), late adolescence (ages 16–18), and adulthood. Scale scores range from 0 (no impairment) to 6 (severe impairment) for each item. Mean Premorbid Adjustment Scale scores for the group were as follows: childhood, 1.3 (SD=0.9); early adolescence, 1.4 (SD=0.9); late adolescence, 1.7 (SD=1.2); adulthood, 1.8 (SD=1.4). Mean premorbid adjustment scores were not significantly associated with age at onset, mode of onset, or duration of illness since either psychiatric or psychotic symptoms began. Poorer premorbid adjustment levels during early and late adolescence were significantly correlated with a lower level of remission (table 2). This pattern was repeated with regard to time to remission, although these relationships did not reach statistical significance (table 1).

Duration of illness was also not correlated with age at onset, mode of onset, or severity of illness at study

entry. In addition, baseline severity of illness was not independently associated with outcome, as measured by either time to treatment response or level of remission.

DISCUSSION

The results of this study indicate that duration of illness prior to treatment, particularly following the onset of psychotic symptoms, may be an important predictor of outcome in first-episode schizophrenic and schizoaffective patients. Duration of psychotic symptoms before treatment was significantly associated with both time to remission and level of remission (complete, partial, or none), with longer duration predicting greater time to remission as well as a lesser degree of remission. Longer duration of illness since onset of any prodromal symptoms was also associated with poorer treatment response (degree of remission). These findings have not, to our knowledge, been previously demonstrated in a well-defined, new-onset study population followed prospectively with uniform follow-up assessments and a standardized treatment protocol.

These results support and extend the findings of the relatively few previous investigations of the impact of duration of untreated schizophrenia (2–9). In contrast, Kolakowska et al. (20) found that outcome in their group of 77 schizophrenic and schizoaffective patients was not related to duration of illness. However, this was a relatively heterogeneous group of both acute and chronic patients studied 2–20 years since the onset of their illness. We caution that outcome in the present study was measured in terms of time to treatment response, as well as level of remission, and not in terms of relapse frequency or social and occupational functioning, all of which are potentially important factors in assessing outcome (11, 21).

The gender difference in duration of illness (more than twice as long for males as for females) that we found in this study suggests that this variable could have a particularly important prognostic significance

for male first-episode schizophrenic and schizoaffective disorder patients.

Consistent with most previous studies (11, 20, 22–24), early age at onset was found to be an unfavorable prognostic feature. On the other hand, mode of onset (measured as the time interval between onset of any prodromal symptoms and onset of psychotic symptoms) did not have any prognostic significance in this study. However, the finding of a typically prolonged mode of onset in our first-episode subjects—almost twice the mean duration of frank psychotic symptoms—was unexpected and provides further evidence for the presence of a substantial prepsychotic prodromal period before the first episode of schizophrenia (10, 25). Further characterization of these prodromal symptoms, as well as their potential patterns of evolution, may be clinically important (26).

Other factors that were not specifically investigated in the present study, but which could account for the apparent relation between duration of acute symptoms and outcome, must be considered. Surprisingly, the mean duration of illness was 52 weeks since the onset of psychotic symptoms and 151 weeks since the onset of any prodromal symptoms. These findings suggest that patients can exist in the community for extended periods with substantial levels of psychopathology. Although predominantly disease-specific factors may determine the onset of illness, many sociocultural and psychosocial factors can determine when and how the patient is brought for evaluation and treatment. For example, less educated families may tolerate psychopathology to a greater extent and may seek medical attention for patients only when their symptoms become severe and/or socially disruptive. In addition, a gradual or insidious mode of onset may be associated with less severe or disruptive symptoms that do not attract attention or necessitate intervention.

Factors related to age at onset, diagnosis, and gender can similarly account for delay in seeking and obtaining treatment. In the present study, male gender was associated with a significantly longer duration of psychotic symptoms prior to treatment. Age at onset and diagnosis were not significantly associated with length of illness before treatment. However, there may presumably be greater tolerance in families and the community for deviant behavior among adolescents than among adults, enabling patients who become ill earlier to remain symptomatic longer before receiving treatment. Patients whose psychopathology has affective components may have more florid symptoms, which attract attention and result in earlier intervention. MacMillan et al. (27) found some association between higher levels of emotional arousal in the family environment and longer duration of illness before hospital admission in a sample of first-episode schizophrenic patients. This finding, as interpreted by Mintz et al. (28), suggests that expressed emotion may play a mediating role in the outcome of patients with longer illness. Duration of illness may also be a function of insight, with many patients lacking insight into their illness and thus postponing seeking treatment.

The finding that outcome may be affected by duration of acute symptoms prior to treatment suggests a role for at least some illness-related factors in schizophrenia. Although speculative, these findings suggest that an active morbid process might occur during periods of acute symptoms or decompensation which, if not ameliorated by neuroleptic drug treatment, may result in lasting morbidity. It is possible that an extended period of dopaminergic neural dysfunction may result in a more severe, or less reversible, pathophysiologic condition. Support for this hypothesis may be gained from preclinical studies of chronic treatment with dopamine agonists and antagonists, which have been shown to alter dopaminergic neural function on a persisting basis (29). These studies have demonstrated enduring behavioral and neurophysiologic effects in animal models, attributed to mechanisms of sensitization, neurotoxicity, and oxidative stress (30, 31).

Crow et al. (2) have raised the question of whether extended duration of illness is more likely to occur in illnesses that have a poor prognosis in any case or because improved outcome is related to earlier institution of treatment; that is, is there a causative relation between longer duration of illness and poorer outcome? Support for the effect of pretreatment length of illness on outcome was provided by the results of this study, since duration of psychotic symptoms prior to treatment was the only variable in the Cox regression model that was significantly associated with time to remission. In addition, duration of illness was positively correlated with another outcome measure, level (or degree) of remission. Premorbid adjustment, age at onset, mode of onset, and severity of illness at presentation were not associated with length of illness, suggesting that this variable is not simply a marker for other illness features which could account for the outcome variance.

These findings suggest that duration of illness prior to initial treatment should be included, as a potentially important predictive variable, in studies concerned with the outcome of schizophrenia. Since earlier neuroleptic treatment appears to be associated with more favorable outcome in first-episode schizophrenia, these results provide support for the clinical value of efforts directed at shortening the length of untreated illness in patients with new onset of schizophrenia (6, 32, 33).

Cigarette Smoking in Schizophrenia: Relationship to Psychopathology and Medication Side Effects

Donald C. Goff, M.D., David C. Henderson, M.D., and Edward Amico, B.S.

Objective: The authors' goal was to study the relationship between smoking status and clinical characteristics in schizophrenic patients. **Method:** Seventy-eight schizophrenic outpatients were assessed by a single rater using the Brief Psychiatric Rating Scale (BPRS), the Abnormal Involuntary Movement Scale, and the Simpson-Angus Scale for extrapyramidal symptoms. Current smokers (N=58) were compared with nonsmokers (N=20) on clinical variables by independent t tests and chi-square tests. Differences in outcome variables were tested by multiple analysis of covariance (ANCOVA) with smoking status and gender as factors and age, neuroleptic dose, and caffeine consumption as covariates. **Results:** Seventy-four percent of patients were current smokers and reported a mean of 19 cigarettes smoked per day. Compared to nonsmokers, current smokers were significantly more likely to be men, to be younger, and to have had an earlier age at onset and a greater number of previous hospitalizations. Current smokers and nonsmokers received mean neuroleptic doses of 1160 and 542 mg/day (chlorpromazine equivalents); the difference was significant. Current smokers also displayed significantly less parkinsonism and more akathisia and had higher total scores on the BPRS. Overall multiple ANCOVA demonstrated a significant main effect for smoking status but not gender or the interaction between gender and smoking status. Univariate ANCOVAs demonstrated a significant main effect of smoking status only for the Simpson-Angus Scale score. **Conclusions:** Cigarette smokers receive significantly higher neuroleptic doses, in part because of a smoking-induced increase in neuroleptic metabolism. Smoking is also associated with significant reduction in levels of parkinsonism. Smoking status is a significant factor that should be considered in assessment of neuroleptic dose requirements and neuroleptic side effects.

(Am J Psychiatry 1992; 149:1189-1194)

It is readily apparent to clinicians working with chronic schizophrenic patients that this population is prone to cigarette smoking, often smoking quite heavily. Surveys of schizophrenic patients have demonstrated rates of smoking between 74% and 92%, compared to 35%-54% for all psychiatric patients and 30%-35% for the general population (1-3). Schizophrenic patients smoke at a significantly higher rate than other psychiatric patients even when contributing factors such as marital status, alcohol use, and socioeconomic status are controlled (2). Given the serious health risks associated with smoking, the question of why these patients smoke so heavily is of considerable importance. In addition, as psychiatric inpatient units increasingly adopt no smoking policies, the impact of

cigarette smoking and abstinence requires greater clarification in this patient population.

It has been suggested that the high rate of smoking among schizophrenic patients might reflect the effects of institutionalization, boredom, and poor impulse control (2, 4, 5). Gopaldaswamy and Morgan (1) suggested that smoking is one of the few pleasures available to many schizophrenic patients. These authors also speculated that cigarette smoking might improve underlying psychopathology by enhancing concentration and reducing discomfort from hyperarousal. In their survey of 59 schizophrenic patients, Glynn and Sussman (6) noted that smoking produced relaxation and reduced anxiety in most respondents. Twenty percent of schizophrenic smokers reported that smoking reduced medication side effects, and an equal number reported smoking in response to psychiatric symptoms.

Cigarette smoking may decrease antipsychotic side effects through a pharmacokinetic interaction. Three groups have demonstrated increased clearance of neuroleptics associated with cigarette smoking, ranging from 44% to 67% for orally administered haloperidol

and fluphenazine (7, 8) and 133% for fluphenazine decanoate (8). Most surveys have found a correspondingly higher mean neuroleptic daily dose administered to smokers than to nonsmokers (9–11). Swett and colleagues (5) demonstrated lower levels of chlorpromazine-induced sedation in smokers, which they attributed to lower chlorpromazine plasma concentrations. Similarly, Stimmel and Falloon (12) demonstrated changes in chlorpromazine plasma concentrations and side effects in a schizophrenic patient who stopped and subsequently resumed smoking.

Cigarette smoking might also affect schizophrenic symptoms and antipsychotic actions through the modulation of dopamine activity. Nicotinic acetylcholine receptors have been identified on mesolimbic and nigrostriatal dopaminergic neurons (13). In rats, acute administration of nicotine stimulates release of dopamine in the striatum and nucleus accumbens by acting on presynaptic nicotine receptors (14). Nicotine also acutely elevates levels of the enzyme tyrosine hydroxylase in the nucleus accumbens, indicating enhanced dopamine turnover (15). Some evidence suggests that the stimulatory effect of anticholinergic agents on dopaminergic activity may result in part from an increase in acetylcholine acting on nicotinic receptors (16).

Several studies in the general population have associated cigarette smoking with a significant reduction in the incidence of idiopathic Parkinson's disease (17–21). This may represent a protective effect of cigarette smoking, since smoking behaviors start decades before the onset of parkinsonism. Nicotine has been used in the treatment of postencephalitic parkinsonism (22). While cigarette smoking can produce tremor in normal subjects, tremor is reduced in patients with parkinsonism (23). The relationship between cigarette smoking and neuroleptic-induced parkinsonism is less clear. In a study of 130 psychiatric inpatients, Decina et al. (9) found significantly less parkinsonism in smokers than in nonsmokers, while Wagner et al. (24) found this effect only in schizophrenic patients with a duration of illness less than 7 years. Yassa and co-workers (11) did not find a relationship between cigarette smoking and parkinsonism, but only 11 patients with parkinsonism were identified in their sample of 154 chronic psychiatric patients. In addition, two studies have found increased tardive dyskinesia in smokers versus nonsmokers (11, 25).

Finally, it has also been suggested that patients with schizophrenia may smoke to medicate underlying symptoms of their illness. Two surveys have demonstrated a greater rate of smoking among persons with prior depressive episodes (26, 27). This finding may reflect a specific reinforcing property of nicotine's mood-elevating effect (28). Nicotine also has been reported to cause calming and alerting effects (29–32). In normal subjects, nicotine improves vigilance and efficiency of information processing and may improve learning (33, 34). The effects of nicotine on schizophrenic symptoms and cognition have not been studied directly.

To further characterize factors associated with ciga-

rette smoking in chronic schizophrenic patients, we assessed clinical symptoms and medication side effects in relationship to smoking status and smoking history.

METHOD

The study was conducted in the outpatient clinic of an urban mental health center. All patients with a diagnosis of schizophrenia were invited to participate. Diagnoses were verified by a research psychiatrist using the Structured Clinical Interview for DSM-III-R (SCID) (35). Patients were assessed by a single rater using the Brief Psychiatric Rating Scale (BPRS) (36), the modified Simpson-Angus Scale for extrapyramidal symptoms (37), and the Assessment for Involuntary Movement Scale (AIMS) (38). After completion of these rating scales, a semistructured interview was conducted to obtain information about the chronology of the patient's illness, treatments, and smoking history. Whenever possible, the patient's history was corroborated by the medical record, clinicians, and family members. The average daily intake of all caffeinated beverages was calculated and recorded as cups of coffee consumed per day. Patients were considered current smokers if they reported smoking a minimum of five cigarettes daily over the past 6 months. Former smokers had smoked at this level during a previous 6-month period, and nonsmokers had never smoked at this level.

Baseline comparisons between smokers and nonsmokers were made by using independent *t* tests for continuous variables and chi-square tests for categorical variables. The cohort was restricted to patients receiving neuroleptic treatment for comparisons of medication side effects (Simpson-Angus Scale, akathisia, AIMS). We performed 2×2 multiple analyses of covariance (ANCOVAs) (with gender and smoking as factors and age, caffeine intake, and neuroleptic dose as covariates) using BPRS total score, positive and negative symptoms subscales, Simpson-Angus Scale total score, akathisia score, and AIMS total score as dependent variables. Where overall multiple ANCOVA main effects were significant, univariate ANCOVAs were performed on that main effect. Results are reported for all comparisons that were tested. Former smokers are combined with nonsmokers for comparisons unless otherwise stated.

RESULTS

Eighty-five patients were asked to participate, and 79 consented. One respondent, an exclusive pipe smoker who claimed that he did not inhale, was dropped from the study. Fifty-nine (76%) of the 78 participants were men and 19 (24%) were women. The mean age was 43 years (*SD*=9.5) (range=23–64), and mean duration of illness was 17.7 years (*SD*=8.9) (range=2–40). Seventy-two patients were receiving antipsychotic medication at a mean daily dose of 989 mg (*SD*=963) of chlorproma-

zine equivalents (range=35–3700). Fifty-eight (74%) were current smokers, 11 (14%) were nonsmokers, and nine (12%) were former smokers. Nine (16%) of the current smokers started smoking after the onset of their psychiatric illness. The 58 current smokers reported smoking an average of 28.9 cigarettes per day ($SD=14.7$) and had started smoking at a mean age of 16.7 years ($SD=6.7$).

Current smokers were compared with nonsmokers (former smokers and those who had never smoked) on demographic and clinical variables (table 1). Current smokers were significantly more likely to be male: 49 (84%) were men, compared with 10 (50%) of the nonsmokers ($\chi^2=7.8$, $df=1$, $p=0.005$). Current smokers were also younger, had an earlier age at onset and a greater number of prior hospitalizations, and reported drinking more caffeine per day. Only one subject from each of the two groups acknowledged current or past alcohol abuse, and only two subjects from the current smokers group acknowledged abuse of other substances (both marijuana).

Current smokers scored significantly higher on the BPRS than nonsmokers (table 1). Analysis of subscales of the BPRS (39, 40) revealed current smokers to have higher levels of both positive and negative symptoms. Current smokers did not differ significantly in levels of depression, tension, or excitement as measured by the BPRS.

The seventy-two patients currently receiving antipsychotic medication were compared according to measures of medication side effects. Current smokers were receiving a significantly higher dose of neuroleptic than were nonsmokers (1160 mg/day versus 542 mg/day of chlorpromazine equivalents). The two groups did not differ in mean weight or in the frequency of concurrently prescribed anticholinergic medication. Current smokers displayed significantly less parkinsonism and more akathisia as measured by the Simpson-Angus

Scale. There was a trend for current smokers to exhibit less tardive dyskinesia ($p=0.10$) as measured by the total score on the first eight items of the AIMS.

Overall multiple ANCOVA showed a significant main effect for smoking status ($F=2.44$, $df=5$, 61, $p=0.04$) but not for gender ($F=1.93$, $df=5$, 61, $p=0.11$) or the interaction between gender and smoking status ($F=0.36$, $df=5$, 61, $p=0.87$). Since no significant Gender by Smoking Status interaction effects were found for any dependent variable, main effects could be assessed unambiguously (table 2). A significant main effect of smoking status was found for the Simpson-Angus Scale total score but not for scores on the BPRS total score, positive and negative subscales, akathisia, or AIMS. Of the covariates, caffeine intake was significantly related to the total BPRS score and the positive symptoms subscale but was not related to the negative symptoms subscale, Simpson-Angus Scale, akathisia, or AIMS. Neuroleptic dose was related to the negative symptoms subscale of the BPRS but not to any of the other outcome measures.

DISCUSSION

Our results are consistent with other studies that report high rates of cigarette smoking in schizophrenic patients; the men in our sample smoked at a higher rate than the women (83% versus 47%). Smokers in our sample were prescribed neuroleptic at roughly twice the daily dose prescribed for nonsmokers. This finding is in keeping with the smoking-induced elevation of hepatic clearance of neuroleptic drugs previously described (7, 8, 41). Lacking measures of plasma concentrations of neuroleptics in our two patient groups, we can only infer that neuroleptic activity levels in smokers were comparable to, and perhaps higher than, levels in nonsmokers on the basis of the higher mean level of akathisia

TABLE 2. Univariate Analyses of Variance in Psychopathology Among Smoking and Nonsmoking Schizophrenic Patients

Dependent Variables	F Ratio				
	Factors		Covariates		
	Cigarette Smoking	Gender	Caffeine Intake	Age	Neuroleptic Dose
BPRS total score	1.7	0.05	4.7 ^a	0.4	1.7
Positive symptoms	2.6	0.1	5.4 ^a	0.02	1.0
Negative symptoms	1.1	3.6	0.002	0.003	4.6 ^a
Modified Simpson-Angus Scale for Extrapyramidal Symptoms score	6.5 ^a	3.4	0.02	0.9	0.07

found in the smokers' group. Higher neuroleptic doses administered to smokers may also reflect clinicians' efforts to control resistant psychotic symptoms, as indicated by smokers' significantly higher scores on the BPRS.

Smokers displayed significantly less neuroleptic-induced parkinsonism, a finding that replicates the study by Decina and colleagues (9). In both studies the effect was highly significant and appeared to be independent of gender, age, and use of anticholinergic agents. The lesser frequency of parkinsonism that we observed was impressive considering that it occurred in patients receiving a twofold higher dose of neuroleptic and that it occurred in the presence of higher levels of akathisia. While Wagner and colleagues (24) found lower levels of parkinsonism only in smokers with durations of illness of less than 7 years, we did not find this to be the case in our study. Only eight (10%) of our patients had been ill less than 7 years, and for the cohort as a whole, duration of illness did not correlate with ratings of parkinsonism. The number of cigarettes smoked daily did significantly correlate with ratings of parkinsonism ($r=0.26$, $df=56$, $p=0.02$).

Whether cigarette smoking directly affects parkinsonism is uncertain. However, just as smoking in the general population appears to protect against onset of idiopathic parkinsonism in later age, smokers in our cohort had begun smoking on average 8 years before starting neuroleptic therapy. This temporal relationship argues in favor of a possible antiparkinsonism effect of smoking, rather than a tendency for patients to smoke in response to extrapyramidal symptoms. It is unlikely that smoking-induced reduction in neuroleptic plasma levels accounts entirely for this effect. Whereas nicotine may reverse some cognitive side effects of anticholinergic agents (42), anticholinergic treatment of smokers and nonsmokers did not differ and so does not account for the antiparkinsonism effect of smoking.

In contrast to the evidence suggesting an antiparkinsonism effect in humans, animal models indicate that nicotine may worsen extrapyramidal symptoms acutely, as nicotine produces catalepsy in mice and enhances neuroleptic-induced catalepsy in rats (17, 43). When administered chronically, nicotine protects against 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine

(MPTP)-induced degeneration of nigrostriatal dopamine neurons in mice, which is an animal model for parkinsonism (44). It has been suggested that nicotine decreases vulnerability of nigrostriatal neurons by desensitizing excitatory nicotinic receptors, thereby reducing firing rates and energy demands of these neurons (45, 46). In addition, nicotine may reduce symptoms of parkinsonism acutely by enhancing release of dopamine in the striatum (47) and, after chronic administration, by lowering brain levels of acetylcholine (48).

The higher level of psychosis in smokers than in nonsmokers, as measured by the positive symptom subscale of the BPRS, was found to be nonsignificant when caffeine intake was controlled for by multiple ANCOVA. Cigarette smoking and caffeine intake correlate in normal subjects as well as in psychiatric patients (49). In our cohort, the number of cigarettes smoked daily correlated with the daily intake of caffeine at the trend level ($r=0.23$, $df=56$, $p=0.05$). Lucas and co-workers (50) recently reported that acute administration of caffeine to schizophrenic patients elevated scores on the BPRS, including positive symptoms such as thought disorder and unusual thought content. However, attempts to demonstrate a psychotogenic effect of caffeine when it is administered over more extended periods have produced inconsistent results (51–53). Mathew and colleagues (54) found significant reductions of cerebral blood flow in schizophrenic patients given a single dose of caffeine but did not observe change in clinical status. Thus, although caffeine use was associated with elevations of psychosis in our cohort, there is little evidence to suggest that caffeine directly contributed to a worsening of clinical status.

Hughes and colleagues (2) noted that cigarette smoking was associated with more severe illness in a heterogeneous sample of psychiatric patients. It has been suggested that schizophrenic patients may smoke in response to symptoms of their illness, as described by 20% of patients interviewed by Glynn and Sussman (6). Normal subjects smoke more heavily when stressed or while experiencing discomfort, possibly reflecting nicotine's reported anxiolytic and antidepressant effects (55). Nicotine also improves concentration and decreases distractibility in normal subjects evaluated with the Stroop Test (34, 56). Patients with schizophrenia

have been shown to be particularly impaired in their performance on this test (57, 58), raising the possibility that schizophrenic smokers may be self-medicating a cognitive deficit. The higher degree of psychiatric impairment in the smokers in our cohort may also reflect levels of impulse control insufficient to stop smoking as well as a lack of motivation, particularly if smoking improves symptoms of their illness or provides one of their few sources of pleasure. Self-medication of more subtle cognitive or affective symptoms during adolescence, before the onset of overt psychotic illness, may also contribute to the higher rate of smoking in schizophrenic patients.

Finally, it has been suggested that persons with histories of affective illness are more likely to smoke because of the antidepressant effect of nicotine and are less likely to stop smoking because abstinence may trigger depressive symptoms (26–28). It is surprising that smokers in our cohort did not score higher than nonsmokers on depression or tension items of the BPRS, despite scoring significantly higher on positive and negative symptoms. It is possible that smoking selectively improves affective symptoms in these patients and that attempts to quit may be thwarted by worsening of these symptoms.

Unlike two prior reports, we did not find more tardive dyskinesia in smokers. The patient samples in which this relationship was found differed from ours in that they consisted of inpatients, were diagnostically heterogeneous, and had lower overall rates of cigarette smoking (11, 25). In addition, the smokers studied by Binder and coworkers (25) were receiving neuroleptic at doses equivalent to doses received by nonsmokers; it is possible that smoking-induced lowering of neuroleptic blood levels in smokers may have resulted in less masking of tardive dyskinesia. While several studies in the general population have demonstrated less parkinsonism in smokers, we are aware of only one study that demonstrated more spontaneous orofacial dyskinesias in smokers (59). Such a finding is complicated by the association of dyskinesia with chronic obstructive pulmonary disease, which may be a consequence of smoking (60).

Our findings must be regarded with some caution. We found that it was generally not possible to blind the rater to the smoking status of patients, so rater bias may have influenced our results. However, the lack of more tardive dyskinesia in smokers and the greater level of positive symptoms were both contrary to our expectations and so were unlikely to represent rater bias. More difficult to assess is whether additional, unmeasured variables may have influenced our findings. Smoking was associated with a number of important factors, such as gender, age, and caffeine consumption. We were able to demonstrate statistically that cigarette smoking remained significantly associated with the level of parkinsonism when each of these factors was controlled. Alcohol and other substance abuse has been associated with smoking in other studies (49) and has been reported at rates as high as 58% in patient populations similar to our cohort (61, 62). The extremely

low rates of substance abuse reported by subjects in our study probably represent underreporting and may have obscured substance abuse as a factor contributing to the association between greater psychopathology and cigarette smoking.

CONCLUSIONS

Three practical conclusions can be drawn from this and other related studies. First, smoking status and caffeine intake are important variables that should be addressed when evaluating data from studies of neuroleptic dose, efficacy, and side effects. Second, work should be continued to identify factors that reinforce smoking behavior in schizophrenic patients so that attempts to reduce their exposure to this serious health risk may be more successful. Finally, if the higher rate of smoking in schizophrenic patients reflects in part self-medication of underlying psychopathology or of medication side effects, we must be cautious in abruptly subjecting schizophrenic smokers to smoke-free therapeutic environments, where symptoms of nicotine abstinence may cloud the clinical picture. Alternative methods for delivering nicotine to these patients may also deserve our attention.

Sylvian Fissure Size in Schizophrenia Measured With the Magnetic Resonance Imaging Rating Protocol of the Consortium to Establish a Registry for Alzheimer's Disease

Joseph M. Schwartz, M.D., Elizabeth Aylward, Ph.D., Patrick E. Barta, M.D., Ph.D., Larry E. Tune, M.D., and Godfrey D. Pearlson, M.B., B.S.

***Objective:** Since previous work indicated smaller than normal temporal lobe structures in schizophrenic patients, the authors tested the hypothesis that this abnormality might be reflected in abnormally large sylvian fissures. **Method:** The subjects were 48 schizophrenic patients and 51 normal comparison subjects matched groupwise with regard to age and sex. CSF spaces (sylvian fissures, temporal lobe sulci, temporal horns, third ventricle, lateral ventricles, and superficial cerebral sulci) were visually assessed with the magnetic resonance imaging rating protocol of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD). **Results:** The sylvian fissures of the schizophrenic patients were found to be bilaterally wider than those of the comparison subjects. There were no other significant differences. **Conclusions:** Schizophrenic patients appear to have larger than normal sylvian fissures, which may reflect smaller superior temporal gyri.*

(Am J Psychiatry 1992; 149:1195-1198)

When J. Hughlings Jackson proposed in the late nineteenth century that specific brain regions are involved in the pathogenesis of some psychiatric illnesses (1), there was scant evidence to support this hypothesis. Since then, neuropathological studies (2) have shown smaller than normal temporal lobe structures in schizophrenia. Recently, workers in our laboratory (3) showed smaller than normal superior temporal gyri in schizophrenic patients and correlated this to the severity of auditory hallucinations. Since the sylvian fissure overlies the superior temporal gyrus, it would not be surprising if their sizes were inversely proportional. While the finding of large ventricles is well established in schizophrenia (4), few studies have specifically addressed wider than normal sylvian fissures (5, 6).

In the current study we compared the appearance on

magnetic resonance imaging (MRI) scans of cortical and subcortical CSF spaces, including the sylvian fissure, in patients with schizophrenia and in normal comparison subjects according to the MRI rating protocol of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) (7). This protocol was developed to assess brain atrophy in patients with Alzheimer's disease but, as a standardized method for evaluating the size of CSF spaces, is also applicable to other groups (8).

METHOD

Subjects

The participants in the study were 48 schizophrenic patients and 51 normal comparison subjects. The patients met the criteria for schizophrenia of the Structured Clinical Interview for DSM-III-R (SCID) (9). Each had been hospitalized at least once for this illness but was currently living in the community and receiving outpatient treatment, including neuroleptic medication. No patient had received ECT. The normal comparison subjects were recruited by advertisement and were screened with the SCID. No subject had a history of any of the following: CNS illness, head injury causing unconsciousness for more than 1 hour, headaches of sufficient severity to re-

Received Jan. 16, 1991; revision received Jan. 8, 1992; accepted Jan. 31, 1992. ^aSignificant main effects for diagnosis ($F=19.33$, $df=1$, 97 , $p<0.001$) and for side ($F=21.09$, $df=1$, 97 , $p<0.001$); the interaction was not significant ($F=2.23$, $df=1$, 97 , $p=0.13$).

^b0.0=no atrophy, 3.0=most severe atrophy.

^c $2 \times k$ chi-square test, where $k \leq 7$ (k =number of rating categories used in evaluating each of the CSF spaces). Significance defined as $p<0.0045$ with Bonferroni adjustment.

^dHigher mean rating for the right side than for the left side in both the schizophrenic patients (paired $t=-3.68$, $df=47$, $p=0.001$) and the normal subjects (paired $t=-2.68$, $df=50$, n.s.).

quire medical consultation, heavy alcohol or street drug use in the last 12 months, high-dose oral steroid use in the preceding 3 months, or loss of 25% or more of original body weight in the past 12 months.

The subjects were compared groupwise with regard to age and sex; no significant differences were found. The mean age of the schizophrenic patients was 31.5 years ($SD=7.6$, range=18–51), and the mean age of the comparison subjects was 30.3 years ($SD=7.5$, range=18–47) ($t=0.78$, $df=97$, n.s.). Males constituted 67% and 76% of the schizophrenic and comparison groups, respectively ($\chi^2=2.5$, $df=1$, n.s.).

Procedure

We obtained 5-mm-thick, T_2 -weighted (repetition time=2500–3000 msec, time to echo=80–100 msec), axial MRI scans on one of two identical 1.5-tesla GE Signa scanners. The scans were rated by the principal investigator (J.M.S.) under the supervision of a member of the CERAD neuroimaging task force, according to the 1989 draft of the CERAD MRI rating. This method provides photographs of representative MRI scans illustrating atrophic changes of the following CSF spaces: sylvian fissures, temporal lobe sulci, tips of the anterior temporal horns, third ventricle, bodies of the lateral ventricles, and superficial cerebral sulci.

Because many scans fall between these ratings, the developers of the protocol recommended the addition of intermediate ratings. We selected representative scans for intermediate ratings by consensus, thus expanding the number of possible ratings from the origi-

nal four to a total of seven, with 0.0 indicating no atrophy and 3.0 indicating the most severe atrophy. To qualify for a particular rating a structure had to have atrophy that was equal to or greater than that of the representative scan. All structures except the third ventricle were rated separately for each hemisphere.

The rater who assessed the scans was blind to diagnosis. A randomly selected group of 16 scans were re-rated. The values from the first and second ratings were compared, and the kappa coefficient for intrarater reliability was determined to be 0.60 or greater for all measurements.

RESULTS

Table 1 displays the ratings and chi-square values for the structures in the schizophrenic and comparison groups. We performed a $2 \times k$ chi-square analysis in which k was the number of rating categories ($k \leq 7$) used in evaluating each CSF space. Table 2 displays the rating distributions for the right and left sylvian fissures. The schizophrenic patients demonstrated bilaterally wider sylvian fissures, even after Bonferroni adjustment. There were no other significant differences.

In the schizophrenic patients the mean sylvian fissure rating for the right side was significantly higher than the rating for the left, and a nonsignificant difference in the same direction was seen in the comparison subjects (see table 1). A two-way repeated measures analysis of variance, using sylvian fissure rating as the dependent variable, indicated significant main effects for

both diagnosis (schizophrenic versus normal) and side (left versus right). The Diagnosis by Side interaction was not significant.

DISCUSSION

Previous studies have demonstrated wider than normal sylvian fissures in both hemispheres of schizophrenic patients. Pandurangi et al. (5) quantified the maximum width of the sylvian fissures shown by CT in 23 male schizophrenic subjects and 23 male comparison subjects. McCarley et al. (6) visually assessed the CT appearance of CSF spaces, using a 0–4 scale, in nine male schizophrenic patients and nine male comparison subjects, and they also found that the right sylvian fissure was wider than the left in the schizophrenic subjects; unlike us, however, they did not find a similar pattern in the comparison subjects.

Our study has the advantages of the superior spatial resolution of MRI and more subjects, including both men and women. In addition, we used a standardized MRI rating protocol.

Our observation of larger sylvian fissures in schizophrenic patients was subtle, although significant. It is not clear whether this reflects general differences in temporal lobe size between the two groups. Quantitative measures performed in our laboratory (3) indicate a slightly but significantly smaller superior temporal gyral volume in schizophrenic patients than in normal subjects. Unfortunately, relevant volume measurements and indexes of symptom severity were not available for a substantial number of the patients in the current study. Therefore, we did not correlate these with sylvian fissure size.

If a relationship between sylvian fissure size and temporal lobe volume exists, it could reflect either atrophy or hypoplasia. The evidence (10, 11) favors the hypothesis that the structural difference in the brains of schizophrenic subjects is static and due to an early insult or developmental anomaly. However, large sylvian fissures might favor atrophy since CSF space enlargement accompanies shrinkage of surrounding brain mass, whereas a static defect early in development might not change the relationship of the sizes of the fissure and gyrus.

Several studies (12, 13) have suggested lateralized temporal lobe pathology (more on the left) in schizophrenia. Our study does not support these findings. Our failure to replicate the finding of significantly larger than normal ventricles probably reflects the superior sensitivity of previous studies (3, 4), although in our study there was a tendency toward larger ventricles in the schizophrenic patients.

A major limitation of this study was that the subjects had a relatively narrow range of atrophy ratings. This raises doubts about the applicability to schizophrenic patients of a rating scale developed for use with Alzheimer's disease patients, who show a broader range of atrophy.

TABLE 2. Distribution of Ratings of Sylvian Fissure Atrophy in Schizophrenic and Normal Subjects Rated With the MRI Protocol of the Consortium to Establish a Registry for Alzheimer's Disease

Rating of Sylvian Fissure Atrophy ^a	Number of Subjects	
	Schizophrenic (N=48)	Normal (N=51)

0.5	25	13
1.0	4	0
Left		
0.0	30	46
0.5	18	5

^a0.0=no atrophy, 3.0=most severe atrophy.

The CERAD protocol was chosen because our previous experience with it had shown it to be a reliable way of assessing CSF spaces. It is possible that subtler differences could have been revealed by using rating scales with finer gradations developed specifically for schizophrenia. The suggestion to add intermediate ratings is part of the protocol as furnished by CERAD, but representative scans for these were not provided. These were selected specifically for this study by consensus among the authors. We attempted even finer gradations by adding multiple fractional ratings in the range of values we obtained in our patient group but found that we could not reliably rate scans once the gradations became finer than the ones used in this study.

We must conclude that we are approaching the limits of reliability inherent in the use of a visual assessment scale. One developed specifically for schizophrenia would require gradations broad enough that measurements could be made reliably, and it would probably resemble the first few rating categories of the CERAD protocol. At least for this population, the advantages of quantitative volumetric measurements are clear.

Predicting Feasibility of Day Treatment for Unselected Patients Referred for Inpatient Psychiatric Treatment: Results of a Randomized Trial

Herman Kluiters, Robert Giel, M.D., Fokko J. Nienhuis, Marjolijn Rüphan, and Durk Wiersma, Ph.D.

***Objective:** Because previous studies of day treatment as an alternative to inpatient treatment had major disadvantages or methodological shortcomings, the authors conducted a randomized controlled trial to estimate and predict the extent to which day treatment is feasible for unselected patients referred for inpatient treatment. **Method:** Of 160 patients, 57 were randomly assigned to the control condition and 103 were assigned to the experimental condition. Control patients received standard clinical care. In the experimental condition, day treatment was attempted as soon as the patient's condition permitted. The average number of nights per week that experimental patients spent away from the hospital was compared to the average number of nights away for patients under standard care. **Results:** Day treatment was satisfactory for 40% of the experimental patients but was completely infeasible for another 40%. The level of surveillance needed in the first week, physical illness, number of previous admissions, depressive symptoms, and treatment by qualified psychiatrists versus registrars were variables predictive of these differences. **Conclusions:** In this unselected group of patients, no absolute contraindications against day treatment were found. This suggests that the selection criteria applied in nearly all other controlled studies on the subject were unwarranted. The approach used in this study facilitated treatment in the least restrictive environment possible.*

(Am J Psychiatry 1992; 149:1199-1205)

Every psychiatric treatment modality should face two basic questions: For which categories of patients is it feasible? and How does it affect their psychosocial functioning?

Neither question has yet been answered conclusively for day treatment as an alternative to inpatient treatment. In nine controlled inquiries (1-12) over more than 25 years, day treatment has been studied for a total of 545 patients referred for hospitalization. Nearly one-half participated in the two oldest studies (1-4), which are not well documented. With one exception (1, 2), the patient groups have been selected too stringently to permit unmitigated conclusions. Authors of reviews who have claimed that the second question has been fully (13-15) or partially (16, 17) decided in favor of such day treatment have neglected the limited generalizations that can be drawn from the subjects studied.

Zwerling, Wilder, and Levin (1, 2) conducted the

only controlled study in which the two questions have been addressed conjointly for an unselected group referred for full-time hospitalization, but this study had shortcomings. The randomization ratios fluctuated during enrollment (1), which is undesirable from a methodological point of view (18). Outcome measurement was limited to unstandardized ratings of the patient's psychiatric status and family adjustment by the patient and/or a relative, and these ratings were not assessed at baseline (2). Several essential sociodemographic data were not reported, so evaluation of the equivalence of the control and experimental groups was impossible (1, 2). Nevertheless, this study was important because it did not exclude any patients considered for admission, approaching each patient with the intention to use alternative treatment. This enabled a comparison of patients for whom day treatment turned out to be feasible with those who could not be treated according to that alternative.

Five additional randomized studies on day treatment as an alternative to hospitalization have been published (3-9). Three others applied a weaker design (10-12), comparing patients directly referred to day treatment with globally equivalent groups of inpatients. Such nonrandom allocation can easily produce unbalanced groups (18), as occurred in one study (10): 37% of the

patients in the inpatient group, but only 10% in the day treatment group, were from the lowest social class.

All of the studies since 1970 (5–12) were primarily outcome studies of rather stringently selected groups of patients. Stringency, in terms of the percent of potentially eligible patients actually included, is shown in table 1 for each of the randomized studies. Corresponding percentages were not available from the reports on the other three inquiries. Their selection criteria did, however, not differ essentially from those in the randomized studies. Thus, the generalizability of effects identified by these studies appears to be seriously limited; statements as to feasibility of day treatment are necessarily restricted to minorities of patients referred for admission. Only two reports (5, 9) provided (scarce) data on the randomly assigned patients who could not be fully maintained in day treatment.

The typical day treatment patient studied under controlled conditions appears to be not very ill, to not be very violent, to not be homicidal or noncompliant, to have intact family relations, to not live alone, to be able to rely on someone to provide care, to have no physical illness, to be under 65 years of age, to not be certified, and to be female. (An overview of the distributions of sociodemographic and psychopathological variables in the reviewed studies is available from H.K.) The same impression emerges from uncontrolled studies (19–22) attempting to differentiate patients referred for full hospitalization from those referred to day treatment facilities designed to avoid inpatient care.

We conducted a randomized controlled trial in the Netherlands to evaluate the feasibility and effects of day treatment as an alternative to inpatient care. It can be seen as a replication and expansion of the study by Zwerling, Wilder, and Levin (1, 2).

METHOD

Study Design

From November 1986 to March 1988 a total of 160 patients were randomly assigned to two conditions. All patients were referred for inpatient treatment by psychiatric outpatient services or their general practitioners, except four who were self-referred. Data from the case register showed that the referral pattern during the period of enrollment did not differ from that in the 2 years before the study.

Randomization occurred immediately after acceptance of the patient for admission. Assignment was in blocks of 14 patients, with a fixed ratio of nine experimental to five control subjects, resulting in 103 experimental and 57 control patients. Allocation of the majority of the patients to the experimental condition has distinct advantages when it is unclear whether the experimental treatment can be applied to all patients who are eligible (23, 24).

Standardized measures of psychopathology and social functioning were assessed at entry and at 1 and 2 years; the patient's and a relative's satisfaction with treatment and the burden on the family were also assessed. A regional psychiatric case register recorded all contacts of each patient with mental health care providers and institutions during the 2 years of follow-up.

The research team operated independently of the treatment teams.

Patients

Two categories of patients were excluded from the study: forensic patients assessed at court request (because they

were not admitted for treatment) and patients suffering from any form of dementia. The latter were referred to special institutions. Their exclusion was made explicit, since they might be admitted because of an initially false diagnosis. All other admitted patients from a designated catchment area were included, irrespective of age, certification, or any other variable. Zwerling and Wilder's patient group (1) probably matches our cohort best; the scarcity of published data from their study prohibits a definite conclusion. The semiurban catchment area of 95,000 inhabitants is located in the northeastern part of the Netherlands. It is less prosperous than other areas and has a relatively high rate of unemployment.

Essential psychopathological and sociodemographic data are presented in table 2. The total group did not differ from all patients admitted to psychiatric hospitals

in the Netherlands in 1984. The experimental and control groups were statistically equivalent on *DSM-III* diagnoses and sociodemographic characteristics. The last column shows corresponding data adapted from the Zwerling and Wilder study for their experimental patients only. Information on their control subjects was not published. Our study includes more patients with three or more previous admissions and fewer admitted for the first time. The *DSM-III* diagnoses we report are, of course, only roughly comparable to the diagnoses in the Zwerling and Wilder study.

Conditions

The trial was conducted in a modern 500-bed psychiatric hospital. In the control condition, the patients

^a $z=5.04$, $p=0.0000$ (Mann-Whitney test for independent samples). The mean for the patients who received full-time hospitalization was 1.02 nights ($SD=1.02$), and for the experimental patients it was 3.17 nights ($SD=3.54$).

were treated according to standard hospital care, which included 24-hour hospitalization, medication, regular contacts with a psychiatrist, occupational therapy, and in selected cases, individual, group, behavioral, creative, or psychomotor therapy.

In the experimental condition, day treatment was initiated 1) at once, 2) after some time had elapsed, or 3) not at all, depending on the patient's condition and social situation. The patient's condition and social situation were assessed by a team headed by a psychiatrist or registrar. Close relatives or the patient's partner were asked to be present. The procedure also served to provide the patient and the relatives with extensive information about the support available. On that occasion it was decided by the available parties whether to initiate day treatment at once or to postpone that decision to a later date. All decisions then and later were the final responsibility of the attending psychiatrist or registrar. (In the Netherlands a registrar is a physician seeking registration as a specialist; in psychiatry a 4-year training is required.) The general clinical criterion for keeping a patient in the hospital overnight was danger to self or to others.

The day treatment lasted from 8:30 a.m. to 4:30 p.m. (weekends excluded). It was provided either in a new day center on the hospital grounds, with a specialized multidisciplinary program, or in a regular clinical unit. During day treatment, nights in the hospital could be prescribed; such a prescription was based on the same criteria and authority as previously stated. While the patient was at home, staff could be contacted by telephone on a 24-hour basis. The hospital staff collaborated with the regional psychiatric service outside the hospital, which could at all times render assistance at home and was involved in aftercare (25).

Measures

Feasibility was defined as the average number of nights per week patients spent away from the hospital

according to plan. The average number of nights was calculated by dividing the sum of the nights away from the hospital by the duration in weeks of the treatment episode. This procedure served to render patients with treatment episodes of different durations comparable. This yields a maximum score of 7 for patients fully in day treatment and a minimum score of 0 for patients fully hospitalized. For the control group, this variable denotes the average number of night leaves given in standard care.

This information was missing for eight patients; no differences were found between them and the other patients.

Zwerling and Wilder (1, p. 171) constructed an ordinal variable not fully comparable to ours. Their category II, which included patients (22%) who were transferred to wards more than once or were transferred once for more than 2 nights, covers a wide range; for instance, 12 of their patients were boarded longer than 14 nights, but how much longer was not reported.

For reasons explained further on, the predictor variable "level of patient's protection" was determined. It was measured on a 6-point scale: 6=no need of surveillance; 5=surveillance at fixed times at the group level; 4=permanent surveillance at the group level, occasional interruptions possible; 3=permanent surveillance at the group level; 2=permanent surveillance at the individual level most of the time and on the group level some of the time; and 1=permanent surveillance at the individual level all of the time. Scores for the morning, afternoon, evening, and night of each day of treatment were provided by the attending nurses. The observation sheets used were tested extensively in a pilot study on 40 patients.

Data Analysis

Distributions of the feasibility variable in the control and experimental conditions were determined. The hypothesis that the experimental patients would rank higher on this variable was evaluated with the Mann-Whitney test for rank orders (one-tailed, $p<0.01$).

Predictors of differences in feasibility among the experimental patients were explored with analysis of variance (ANOVA), simple correlation, multiple regression, and discriminant analysis.

RESULTS

Table 3 shows that the average number of nights the patients in the experimental condition spent away from the hospital substantially exceeded the average for the control subjects. More than one-third of the control subjects did not leave the hospital at all during their episodes of treatment; 59.8% of the experimental subjects spent more than 2 nights a week away from the hospital, compared with 16.4% of the control subjects. If it is considered desirable for patients to be treated in the least restrictive environment possible, this constitutes an important dif-

ference. We consider the 40.2% of the experimental patients who left the hospital no more than 2 nights a week on average as unsuitable for day treatment. A satisfactory degree of day treatment, i.e., more than 4 nights at home per week on average, was attained by 39.2% of the experimental patients. As stated before, the results from the Zwerling and Wilder study (1) are not quite comparable to ours as their outcome variable was less specific. Their results were as follows: 34% of their experimental patients were treated entirely on wards, 22% needed more than one transfer to wards or one transfer lasting longer than 2 nights, an additional 5% were transferred once to hospital wards for 1 or 2 nights, and 39% were fully in day treatment.

Test results for the potential predictors of the feasibility of day treatment, assessed with one-way ANOVA, are

shown in table 4. Several variables thought to contraindicate day treatment did not appear to be prohibitive after all. Most prominent of these—and common criteria for exclusion—are substance addiction/abuse, compulsory admission, living alone, and old age. All of the subgroups in table 4 had considerably higher mean feasibility values, i.e., spent considerably more time away from the hospital, than the control group. Patients treated by qualified psychiatrists were substantially more successful than patients treated by registrars.

The best single predictor of feasibility was the most liberal level of protection under which the patient could be managed at least once in the first week of treatment ($r=0.54$, $df=89$, $p<0.001$). Average level of protection in the same week was also a good predictor ($r=0.46$, $df=89$, $p<0.001$). The most liberal level, departing from

TABLE 5. Multiple Regression Analysis of Nights Spent Away From the Hospital by Patients for Whom Day Treatment Was Attempted^a

Predictor	Cumulative R ²	Significance of Change	Zero-Order Correlation With Nights Away From Hospital (df=89)	
			r	p
Level of surveillance in first week	0.29	<0.001	0.54	<0.001
Physical illness	0.32	<0.05	-0.29	<0.01
Lack of previous admissions	0.36	<0.05	0.19	<0.05
Depressive symptoms as reason for admission	0.39	<0.05	0.28	<0.01

^aF=13.60, df=4, 86, p=0.0000; R²=0.36 after correction for shrinkage.

the average level of protection, implies that the patient's condition has at least once been such that protection could be alleviated. Such quick initial improvement in the first treatment week seems to heighten the patient's chances with day treatment slightly, as is reflected by the greater predictive power of the most liberal level of protection over the average level.

Multiple regression analysis (table 5) identified four predictors that together explained 39% of the variance—36% if corrected for shrinkage (26). The most liberal level of protection possible in the first treatment week emerged again as the most powerful predictor. Physical illness at entry had a negative association with feasibility. If depressive symptoms—irrespective of *DSM-III* diagnosis—were the immediate and main cause of admission, then the patient's likelihood of success in day treatment was increased. Patients accepted for first admission had somewhat better chances too. Variables derived from baseline measurement of psychopathology and social functioning did not increase the multiple correlation.

Two feasibility groups were contrasted by discriminant analysis: a "failure" group, which contained patients who each averaged 4 or fewer nights per week away from the hospital, and a "success" group, who averaged more than 4 nights per week. The analysis yielded a highly significant discriminant function (Wilks's $\lambda=0.77$, $\chi^2=22.01$, df=4, p<0.0002). The discriminant function was dominated by the four variables identified by multiple regression analysis plus the variable indicating whether the patient's doctor was a qualified psychiatrist or a registrar. From the discriminant function, actual group membership could be predicted correctly in 74% of the cases.

DISCUSSION

If success in the Zwerling and Wilder study (1) is narrowed down to their two highest categories of patient

outcome and if our criterion for success is assumed to be equal to theirs, their percentage of successfully treated patients (44%) is similar to ours (39.2%). Creed et al. (9) claimed that 68.7% of their patients were successfully treated with day treatment. If their data are corrected for the rejection of 45% of their patients for day treatment before randomization (see table 1), their success rate is 37.8%. The convergence of these three studies, two without selection criteria and one (9) with more liberal criteria than in the remaining studies, is remarkable. One is tempted to speculate that this 40% success rate constitutes an upper limit. However, more evidence from new studies is needed. Contributions to the comparability of such studies would be more detailed specification of the circumstances under which they are conducted and the application of the same outcome measures, e.g., feasibility as defined in this paper. Preferably, new studies should be coordinated in order to vary circumstances and other variables systematically.

One circumstance specific to our study needs closer attention: roughly one-half of the patients were treated by registrars. These patients spent considerably fewer nights away from the hospital than patients treated by qualified psychiatrists. This fact might reflect the limited professional experience of registrars, inducing feelings of insecurity concerning the risks involved and thus resulting in conservative decisions. The authors of one British report (27) attributed the failure to even start a randomized day treatment experiment mainly to the conservatism of trainee psychiatrists. Our success rate might have been considerably higher if the patients had been treated by qualified psychiatrists only.

The degree of predictability we established, 36% explained variance and 74% correct classifications, is substantial in clinical research. To our knowledge, predictability studies comparable to ours have not been conducted in day treatment settings. Emergency room studies (28) of the decision to hospitalize or not seem most related. The extent to which they succeeded in predicting the decisions reached might corroborate the strength of our findings. In one study (29), 18% explained variance was reported. Another (30) explored differences between clinicians and many other predictors. In the final analysis it succeeded in classifying 96% of the nonhospitalized patients correctly. Only 60% of the patients eventually hospitalized were correctly classified by means of the variables in hand.

We assume that the supportive facilities offered during day treatment episodes contributed highly to the maintenance in day treatment of categories of patients who seem less suited for it, e.g., patients who lived alone and patients who were involuntarily admitted. Practical or psychological support by telephone was available around the clock. If circumstances demanded, day treatment was interrupted by hospitalization for one or a few nights or the regional psychiatric service rendered assistance at home. Agreement to follow day treatment implied the formal guarantee to the patient that he or she could call on these facilities at any time.

If the patient lived with relatives or a partner, the same guarantee applied to them. Such a guarantee had practical meaning, of course, but it also created a psychological climate indicating that an appeal for help would never be turned down.

There is at least one group of patients that has never been explicitly excluded from controlled studies of day treatment: patients admitted for depressive symptoms (this is also true of most uncontrolled studies, e.g., the study by Craft [31], one of the oldest). To the best of our knowledge, no reports have ever indicated that as a group they fail in day treatment. Our study is no exception; of all subgroups, depressed patients had the highest success rate.

Probably our most important finding is that there appear to be no absolute contraindications against day treatment. This finding contradicts the exclusion criteria prevailing in controlled studies. If we accept the premise that each patient is entitled to the least restrictive environment possible, given his or her condition (32), it seems to be well worth considering day treatment as a potential alternative to hospitalization for all patients.

Tardive Dyskinesia in Elderly Psychiatric Patients: A 5-Year Study

Ramzy Yassa, M.D., Christine Nastase, M.D.,
Denyse Dupont, M.D., and Madeline Thibeuau, S.C.

Objective: The authors investigated the prevalence of tardive dyskinesia among elderly psychiatric patients who had never received neuroleptic medication before their first hospitalization. **Method:** The study was performed in the geriatric psychiatry unit of a university-affiliated hospital in Canada and involved all first-admission patients admitted from September 1984 through August 1989 who had never taken neuroleptic drugs. In September and October 1989, the patients who were available for follow-up were examined and given ratings on the Abnormal Involuntary Movement Scale to establish the presence or absence of tardive dyskinesia. The patients' records were reviewed for information on age, diagnosis, duration of hospitalization, neuroleptic treatment received after admission, anticholinergic drugs received, and drug-free periods. **Results:** Of the 162 patients who were available and whose data were analyzed, a total of 99 had been treated with neuroleptics, and 35 (35.4%) of these were found to have tardive dyskinesia. Two of the 35 also had tardive dystonia. Significantly more patients with major depression than patients with primary degenerative dementia or delusional psychosis had tardive dyskinesia. **Conclusions:** This study confirms the higher vulnerability of elderly psychiatric patients treated with neuroleptics to the development of tardive dyskinesia. The authors stress that caution is especially necessary when neuroleptics are prescribed for older patients with major affective disorders.
(Am J Psychiatry 1992; 149:1206-1211)

Tardive dyskinesia, a neuroleptic-induced movement disorder, has been reported to be more prevalent in patients whose medication is started late in their illness (1) and in newly treated elderly psychiatric patients (2-4). Thus, psychiatric patients in the geriatric age group are at risk, and there are some estimates that tardive dyskinesia may develop in a short period in almost half of neuroleptic-treated patients in this age population (4, 5). Although tardive dyskinesia may occur in a large number of elderly psychiatric patients, spontaneous dyskinesia may also occur in an average of 5% of these patients without prior neuroleptic therapy (6). Thus, when these patients are studied, it is important to provide a comparison group of patients who have never received neuroleptics in order to account for the possible appearance of spontaneous dyskinesia.

In our hospital, we have been studying the prevalence of tardive dyskinesia in newly treated elderly psychiat-

ric patients for the past 5 years. In 1988 we reported (4) on a 2-year study that started in September 1984 and ended in August 1986 which involved 78 first-admission patients, 39 of whom received neuroleptics and 39 who never received neuroleptics. Of the patients who received neuroleptics, 16 (41.0%) developed tardive dyskinesia after a mean of 14.8 months (SD=8.3) of continuous neuroleptic therapy. This is a slightly lower proportion than that in a more recent study by Saltz et al. (5), who found that 48.9% of their subjects developed tardive dyskinesia after 48 weeks of cumulative neuroleptic exposure.

The present study extended our previous one (4). We report on the prevalence of tardive dyskinesia in patients who were treated with neuroleptics for up to 60 months (5 years) during the period from Sept. 1, 1984, to Aug. 30, 1989.

METHOD

Patients admitted for the first time to the geriatric psychiatry unit at our hospital (minimum age=65 years; catchment area=300,000 population) who had never received neuroleptics before admission—as confirmed

Presented at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received April 9, 1991; revision received Jan. 28, 1992; accepted Feb. 21, 1992. From the Department of Psychiatry, Douglas Hospital Centre. Address reprint requests to Dr. Yassa, Department of Psychiatry, Douglas Hospital Centre, 6875 LaSalle Blvd., Verdun, Que. H4H 1R3, Canada.

by detailed medication histories obtained from the patients, relatives, and referring physicians—were evaluated for the presence of movement disorders with the Abnormal Involuntary Movement Scale (AIMS) (7). All patients who had received neuroleptics before admission were excluded from the study.

The AIMS measures the severity of tardive dyskinesia on a scale of 0 (no tardive dyskinesia) to 4 (severe tardive dyskinesia) in each of seven body areas. Because the AIMS does not measure dystonia, we also added the dystonia items of the Simpson Rating Scale (8) to the AIMS, as previously described in our tardive dystonia studies (9, 10). We followed the criteria set by Jeste and Wyatt (11) for determining the presence of tardive dyskinesia, i.e., a minimum AIMS score of 2 (mild) for one body area. We used this same criterion as the minimum in our previous studies (1, 12).

Patients admitted for the first time to our unit were also evaluated for spontaneous dyskinesia before they received any neuroleptic treatment and again during the study period, i.e., during September–October 1989.

A total of 251 patients (95 men and 156 women) who had never received neuroleptics were admitted to the hospital for the first time during the period from September 1984 through August 1989. For reexamination for the presence of tardive dyskinesia or spontaneous dyskinesia, patients were visited in their homes, nursing homes, foster homes, outpatient clinics, or inpatient unit. The examiner was blind to their neuroleptic intake since admission to the hospital. Diagnoses were made according to *DSM-III* criteria and were confirmed by two independent investigators using the Hamilton Rating Scale for Depression (13), the Mini-Mental State examination (14) for primary degenerative dementia, and the Brief Psychiatric Rating Scale (15) for delusional disorders.

Following the examination of each patient, the files were reviewed to record whether the patient had received neuroleptics or not, to identify diagnosis, and to study in detail the patient's neuroleptic intake until the end of August 1989. Drug-free periods of 1 month or more were also recorded. (The chart reviews were conducted without knowledge of the patients' current tardive dyskinesia status.) Total neuroleptic time was defined as the total time that a patient received neuroleptic treatment minus the drug-free periods. Neuroleptic dosage was translated into chlorpromazine equivalents with Davis's formulas (16), except for pimozide dose, which was translated into chlorpromazine equivalents (0.5 mg equivalent to 100 mg of chlorpromazine) according to Baldessarini's method (17), and fluphenazine injection (25 mg i.m. every 2 weeks equivalent to 300 mg/day of chlorpromazine), which was calculated according to the formula of Nestoros et al. (18, 19).

RESULTS

During the 5-year period between September 1984 and August 1989, of the 251 first-admission patients

who had not received neuroleptics, 64 (31 men and 33 women) died; their mean age was 79.3 years (range=66–95). Of these, 43 were diagnosed as having primary degenerative dementia, nine bipolar disorder, eight delusional disorder, and four alcoholic dementia. In addition, 25 patients (10 men and 15 women) could not be contacted for the follow-up. Their mean age was 71.5 years (range=70–85). Of these, 18 had diagnoses of major depression, six delusional disorder, and one primary degenerative dementia.

For the final analysis, 162 patients (54 men and 108 women) were available for reexamination during the months of September and October 1989. Of these, 99 (29 men and 70 women) had been prescribed neuroleptics at some point during the 5-year period covered by the study, while 63 (25 men and 38 women) had never received neuroleptics. (Anticholinergic drugs are not prescribed on a prophylactic basis in the geriatric psychiatry unit but were prescribed for some patients as needed.) The mean age of the patients who did not receive neuroleptics was 76.4 years (range=66–95). Of these, 22 had diagnoses of primary degenerative dementia, 38 major depression, one delusional disorder, and two alcoholic dementia.

Prevalence of Spontaneous Dyskinesia

Of the 251 patients admitted for the first time to our unit, 10 (six men and four women) showed evidence of spontaneous dyskinesia before any neuroleptic treatment was instituted. This constitutes 4.0% of the total patient population (6.3% of the men and 2.6% of the women). Their mean age was 77.7 years (range=70–86). Of the 10 patients with spontaneous dyskinesia, five were diagnosed as suffering from primary degenerative dementia, four from major affective disorders, and one from delusional psychosis. All of them exhibited mild bucco-oral movements. No other body areas were affected.

At follow-up, five of the patients with spontaneous dyskinesia had died. Of the other five patients, one had received neuroleptics, and her abnormal movements had disappeared. She also showed no evidence of tardive dyskinesia. Four of the patients who received no neuroleptics continued to exhibit mild bucco-oral movements. Thus, four (6.3%) of 63 patients who received no neuroleptics showed evidence of spontaneous dyskinesia at follow-up.

Prevalence of Tardive Dyskinesia

The characteristics of the patients who received neuroleptics (N=99) are presented in table 1. The patients without tardive dyskinesia were significantly older than the patients with tardive dyskinesia. The prevalence of tardive dyskinesia in the patient population was 35.4% (35 of 99). More men (13 of 29, or 44.8%) than women (22 of 70, or 31.4%) had tardive dyskinesia, but this difference was not statistically significant ($\chi^2=1.6$, $df=1$). However, if we apply the criteria of Schooler and

TABLE 1. Characteristics of 99 Neuroleptic-Treated Patients With or Without Tardive Dyskinesia

Kane (20) for minimum manifestation of tardive dyskinesia (i.e., two areas of the body with a minimum AIMS rating of 2 or one area with a rating of 3), then the prevalence of tardive dyskinesia was 30.3% (30 of 99), and significantly more men (13 of 29, or 44.8%) than women (17 of 70, or 24.3%) exhibited tardive dyskinesia ($\chi^2=4.07$, $df=1$, $p<0.05$).

Eleven of the patients had mild tardive dyskinesia, 21 had moderate tardive dyskinesia, and three had severe tardive dyskinesia (table 2). The bucco-oral area was affected in all 35 of these patients. In addition, six women were affected in their arms or legs. Tardive dystonia (torticollis) was present in two men; their family members did not show evidence of movement disorders. These two patients also had mild bucco-oral tardive dyskinesia. Thus, the prevalence of tardive dystonia in our patients was 2.0%, and 6.9% in the men.

Neuroleptic Intake

Patients who received neuroleptics were treated for a mean of 20.7 months (range=1–60 months). This indicates the duration of actual neuroleptic treatment, excluding drug-free periods. Patients who developed tardive dyskinesia received significantly longer neuroleptic treatment than patients without tardive dyskinesia (table 1).

Of the 99 patients who received neuroleptics, 58 received one neuroleptic: 47 received haloperidol, four received pimozide, three perphenazine, two chlorpromazine, and one each thioridazine and fluphenazine. Of the haloperidol-treated patients, 14 (29.8%) developed tardive dyskinesia. Of the pimozide-treated patients, two developed tardive dyskinesia. No tardive dyskinesia developed when the other medications were given

alone. Of the remaining neuroleptic-treated patients, 31 received two neuroleptics, nine received three neuroleptics, and one received four neuroleptics.

As shown in table 1, patients with tardive dyskinesia also received significantly more total neuroleptic medication than patients without tardive dyskinesia. Men with and without tardive dyskinesia received a greater total amount of neuroleptics than women in the same groups.

Also noted in table 1, the present dose of neuroleptic drug was not significantly different for the patients with and without tardive dyskinesia. Equal proportions of patients with tardive dyskinesia (13 of 35, or 37.1%) and without tardive dyskinesia (24 of 64, or 37.5%) were not receiving neuroleptics at the time of the examination.

Duration of Neuroleptic Therapy

Of the 48 patients who received 1–12 months of continuous neuroleptic treatment, 11 (22.9%) developed tardive dyskinesia, compared to seven (50.0%) of the 14 who received neuroleptics for 13–24 months. Of the 12 patients who received neuroleptics for 25–36 months, four (33.3%) developed tardive dyskinesia, compared to eight (57.1%) of the 14 who received neuroleptics for 37–48 months. Of the 11 patients who received neuroleptics for 49–60 months, five (45.5%) developed tardive dyskinesia.

Eighteen (51.4%) of the 35 patients with tardive dyskinesia developed the side effect within the first 24 months of continuous neuroleptic therapy.

Of the 35 patients with tardive dyskinesia, 12 (34.3%) had drug-free periods, compared to 20 (31.3%) of the

64 patients without tardive dyskinesia. The mean numbers of drug-free months for the two groups were not significantly different (table 1).

Other Factors

Age. As shown in table 2, there was no indication that aging increases the chances of developing tardive dyskinesia. In fact, if we divide the patient population into 10-year age groups, we find that of the 53 patients in the age range of 65–75 years, 23 (43.4%) showed evidence of tardive dyskinesia, compared to 10 (26.3%) of the 38 in the next age group (76–85 years) ($\chi^2=2.79$, $df=1$, n.s.).

Antiparkinsonian medication. Patients with tardive dyskinesia received significantly more antiparkinsonian drugs than patients without tardive dyskinesia, as shown in table 1. Of the 35 patients with tardive dyskinesia, 19 (54.3%) received antiparkinsonian drugs, compared to 20 (31.3%) of the 64 patients without tardive dyskinesia ($\chi^2=4.11$, $df=1$, $p<0.05$, with Yates' correction). Two of the men with tardive dyskinesia, two of the men without tardive dyskinesia, and one woman without tardive dyskinesia received amantadine as their antiparkinsonian agent.

Diagnosis. Of the 99 patients receiving neuroleptics, 49 were diagnosed as suffering from primary degenerative dementia. Of these, 12 (24.5%) were found to have tardive dyskinesia, compared to 12 (60.0%) of 20 with the diagnosis of major depression, a statistically significant difference ($\chi^2=6.41$, $df=1$, $p<0.03$, with Yates' correction). This difference is still significant if Schooler and Kane's criteria are applied (11, or 22.4%, of the 49 patients with dementia and 10, or 50.0%, of the 20 with major depression; $\chi^2=3.87$, $df=1$, $p<0.05$, with Yates' correction). This difference was not due to a longer duration of neuroleptic treatment (for dementia patients, mean=26.3 months, SD=17.4, range=2–53 months; for depressed patients, mean=22.1 months, SD=15.0, range=8–60 months) or to the total amount of neuroleptic treatment in either diagnostic category (for dementia patients, mean=94.8 g, SD=44.1; for depressed patients, mean=67.6 g, SD=27.7).

Of the 23 patients with delusional (paranoid) disorder, six (26.1%) developed tardive dyskinesia. The difference between the proportion of patients with delusional (paranoid) disorder and the proportion with major depression (60.0%) who developed tardive dyskinesia was statistically significant ($\chi^2=4.97$, $df=1$, $p<0.05$). Of the seven patients with alcoholic dementia, five (71.4%) developed tardive dyskinesia.

Other medications. Of the 35 patients with tardive dyskinesia, 12 (34.3%) received no concomitant medications, compared to 42 (65.6%) of the 64 patients without tardive dyskinesia. Antidepressants were prescribed for 16 (45.7%) of the patients with tardive dyskinesia, compared to nine (14.1%) of the patients without tardive dyskinesia. Antihypertensives (mainly diuretics and methyl dopa) were prescribed for five patients with tardive dyskinesia (14.3%) and three pa-

TABLE 2. Distribution of 99 Neuroleptic-Treated Patients by Age Group

Item	Age (years)

Women	15	20	17	11	7

tients without tardive dyskinesia (4.7%). Antidiabetics were prescribed for three patients with tardive dyskinesia (8.6%), compared to two patients without tardive dyskinesia (3.1%). Digoxin was prescribed for three patients with tardive dyskinesia (8.6%) and four patients without tardive dyskinesia (6.3%). Levothyroxine sodium was prescribed for two patients with tardive dyskinesia (5.7%) and one patient without tardive dyskinesia (1.6%). Lorazepam was prescribed for 10 patients with tardive dyskinesia (28.6%) and 19 patients without tardive dyskinesia (29.7%).

DISCUSSION

The prevalence of tardive dyskinesia in an elderly population recruited over 5 years, treated continuously with neuroleptics for a mean of 20.7 months (range=1–60 months), was 35.4%. On the other hand, of 63 patients who received no neuroleptics, four (6.3%) showed spontaneous dyskinesia. These findings are compatible with those in the published studies of comparable patient populations (2, 3, 5).

Although for many years one of the few consistent research findings has been that the prevalence of tardive dyskinesia increases with age, relatively few studies have been devoted to those patients who receive neuroleptics for the first time after age 65. Crane and Smeets (2) found that tardive dyskinesia developed in 39% of 39 patients (median age=74 years, range=63–89) who were followed for a period up to 28 months. Lieberman et al. (3) found that tardive dyskinesia developed in

16.5% of 79 elderly patients who were treated with neuroleptics for 18 months (mean age=85.5 years, range=65–99). Finally, Saltz et al. (5) found that tardive dyskinesia developed in 49% of 84 patients treated with neuroleptics for a mean of 16.7 weeks (mean age=76.6 years, range=57–96). The mean prevalence of tardive dyskinesia in these studies is 34.2%, which is close to the 35.4% in our present study.

Women have been overrepresented in all the studies dealing with elderly psychiatric patients, but we found the prevalence of tardive dyskinesia to be nonsignificantly higher in the men than in the women, if the more liberal Jeste and Wyatt criteria (11) are applied. And, if the Schooler and Kane criteria (20) are applied, tardive dyskinesia appears to have been significantly more prevalent in the men than in the women. Tardive dyskinesia was found to be equally distributed in both sexes in a recent study of a similar patient population (5).

Our study is the first to indicate the prevalence of tardive dystonia in an elderly psychiatric population. We found that tardive dystonia was present in 2% of the treated patients. This corresponds to findings in our previous studies (9, 10), where tardive dystonia occurred in 2% of a younger population.

Spontaneous dyskinesia was found in 4% of our patient population, corresponding to the weighted mean of 4% in the most recent reviews on the subject (6, 11, 21, 22). At the end of the 5-year period we studied, four (6.3%) of 63 patients who never received neuroleptics exhibited spontaneous dyskinesia. None of the 63 patients had developed *de novo* spontaneous dyskinesia or tardive dyskinesia when reexamined.

In our study, we found that patients with tardive dyskinesia stayed longer in the hospital, were treated with neuroleptics for a longer period, and received a larger mean total amount of neuroleptics than patients without tardive dyskinesia. Some studies dealing with younger subjects have identified duration of neuroleptic treatment as a factor in the development of tardive dyskinesia (23–25), whereas others have not (26, 27). It is possible that for our patients with tardive dyskinesia, the larger amounts of neuroleptic medication reflect the longer duration of treatment with these medications.

In some studies (12, 25), drug-free periods have been found to be a factor in the development of tardive dyskinesia, but this was not true in our study.

We were also unable to confirm that the prevalence of tardive dyskinesia increased with age. We found that the younger patients (65–75 years) had a higher but not statistically significant prevalence of tardive dyskinesia than the older patients (76–85 years): 43.4% and 26.3%, respectively. This is consistent with the findings reported recently in a patient group similar to ours, in which aging was not found to contribute to a higher prevalence of tardive dyskinesia (5).

We never prescribe prophylactic antiparkinsonian drugs for our patients. Whenever acute extrapyramidal side effects develop, we prefer to reduce the neuroleptic dosage as a first choice, rather than giving antiparkin-

sonian drugs. Even so, we found that patients with tardive dyskinesia received significantly more antiparkinsonian drugs than patients without tardive dyskinesia, indicating that acute extrapyramidal side effects may develop more in patients with tardive dyskinesia than in those without tardive dyskinesia. A possible reason for the greater amounts of antiparkinsonian drugs received by patients with tardive dyskinesia is that these patients received larger amounts of neuroleptics.

Our study confirms the finding that more patients with affective disorders than patients without affective disorders have tardive dyskinesia. Several studies (28–31) have indicated that patients with affective disorders (particularly depressed patients) are more prone to develop tardive dyskinesia than patients in other diagnostic categories. Our study indicates that this holds true even in an elderly psychiatric population. We found that tardive dyskinesia was more prevalent among depressed patients (60.0%) than among patients with primary degenerative dementia (24.5%) or delusional (paranoid) disorder (26.1%). This higher prevalence of tardive dyskinesia in depressed patients does not reflect the duration or total amount of neuroleptic treatment, and it is difficult at present to speculate on the reason for the higher prevalence in these patients.

In summary, tardive dyskinesia developed in 35.4% of elderly psychiatric patients who received neuroleptics for up to 60 months. We found that gender was not a factor in the development of tardive dyskinesia in this aged population. Patients with tardive dyskinesia, however, received neuroleptics for longer periods and in larger amounts than patients without tardive dyskinesia. They also received more antiparkinsonian drugs, indicating that acute extrapyramidal side effects may be precursors of the development of tardive dyskinesia. More patients with affective disorders than patients in other diagnostic categories developed tardive dyskinesia; thus, clinicians should be cautious when prescribing neuroleptics for these patients.

An Evaluation of the Cleveland Criteria for Inpatient Treatment of Substance Abuse

James R. McKay, Ph.D., A. Thomas McLellan, Ph.D., and Arthur I. Alterman, Ph.D.

***Objective:** This study examined the validity of the Cleveland Admission, Discharge, and Transfer Criteria, a comprehensive system for assigning alcohol- and drug-abusing patients to appropriate levels of care. **Method:** The subjects were 143 alcoholic and cocaine-dependent male patients in an intensive Veterans Administration day treatment program for substance abusers. Patients who should have received inpatient treatment according to the Cleveland criteria were compared with those who were properly "matched" to day treatment according to the criteria. The outcome measures were treatment completion, results of urine toxicology screens, and self-reports of substance use and psychosocial functioning. **Results:** Patients who met the criteria for inpatient care were not more likely to drop out of day hospital treatment, and there was no evidence that they were drinking or using cocaine more frequently during follow-up. Furthermore, they did not appear to be doing worse on any of the other outcome measures, with the exception of psychological status. **Conclusions:** The results suggest that for male substance abusers in the lower socioeconomic levels, the Cleveland criteria may not be effective in differentiating patients who can manage well with day hospital treatment and those who require inpatient treatment.*

(Am J Psychiatry 1992; 149:1212-1218)

One of the more actively debated questions in the field of substance abuse treatment concerns which patients will benefit most from what type of treatment (1, 2). Much of the attention in this area has been focused on differentiating patients who require inpatient rehabilitation from those who can manage equally well on an outpatient or day treatment basis.

Given the greater expense of inpatient treatment (3, 4), as well as the disruption it may entail for patients and their families, outpatient rehabilitation has been seen as the treatment of choice whenever possible. At the same time, the general feeling has been that patients with more severe substance abuse, current psychiatric comorbidity, or severely dysfunctional living situations probably need inpatient treatment (2, 4, 5).

In an effort to improve the matching of substance abuse patients to various levels of care, Hoffman et al. (6) developed the Cleveland Admission, Discharge, and Transfer Criteria, which provide guidelines for assess-

ing patients in seven areas: acute intoxication/withdrawal, physical complications, psychiatric complications, impairments in certain areas of life, acceptance of treatment, loss of control, and recovery environment. Ratings in each of these areas are used to determine the appropriate level of care, ranging from level I (mutual self-help groups) to level VI (medically managed intensive inpatient unit). According to the Cleveland criteria, patients are in need of inpatient rehabilitation (as opposed to intensive outpatient treatment) when they reach a certain level of severity in one or more of the seven areas, or "dimensions."

Treatment providers, as well as third-party payers, are greatly in need of objective, validated guidelines for appropriate patient placement; hence, the Cleveland criteria have generated considerable interest (1). There is some initial evidence for the validity of the criteria. Clinical observation as well as a number of research studies have shown that substance abusers with poorer social supports and greater severity of psychiatric disorder typically show less improvement and poorer post-treatment outcomes with outpatient care than with inpatient treatment (7). However, the Cleveland criteria have not been empirically validated as a comprehensive system for assigning patients to appropriate treatment modalities.

In this study, our goal was to evaluate the Cleveland criteria for inpatient rehabilitation. As part of a recent study comparing the efficacy and costs of inpatient and

^aHigher scores indicate greater problem severity.

day hospital rehabilitation for alcohol- and/or cocaine-dependent patients, we had collected data from patients at admission, during treatment, and at the 4- and 7-month points following intake. An initial examination of the admission data suggested that many of the patients in the day treatment program would have been assigned to inpatient treatment if the Cleveland criteria had been used to match patients to treatments. This group of patients, therefore, would be considered "mismatched" to the day treatment level of care and would be expected to have a higher dropout rate, less improvement, and poorer outcomes than patients treated in the same program who were considered appropriate, or "matched," to that level of care. If these patients did not have worse outcomes, however, it would be difficult to argue that they needed more intensive treatment. The study was thus a test of the validity of the Cleveland criteria for assigning patients to medically supervised intensive inpatient treatment (level V) rather than intensive outpatient treatment (level IV).

METHOD

The subjects were 143 male alcoholic (N=70) or cocaine-dependent (N=73) veterans who were patients in an intensive day treatment program for substance abusers. Patients were not admitted to this program if they were judged by the program physician to have medical or psychiatric problems severe enough to warrant inpatient treatment. In addition, 3% of the subjects who were initially deemed appropriate for day treatment were excluded from participation in the study because of serious medical problems, and 12% were eliminated because of psychiatric problems such as a history of psychosis or dementia.

Of the 143 subjects in the study, 86.7% (N=124) were black and 13.3% (N=19) were white; 23.8% (N=34) were married, and 46.2% (N=66) had worked fewer than 5 days in the month preceding intake. Addi-

tional information on the patients is presented in table 1. For the most part, the alcoholic and cocaine-dependent patients were comparable, with a few notable exceptions. The alcoholic patients were older, a higher percentage of them were white (24.6% versus 2.8%), and they reported more years of regular use of their substance of abuse than the cocaine-dependent patients.

Data Collection

At intake or during the first week of treatment, the subjects were given the following structured interviews, counselors' ratings, and patients' self-report instruments.

Addiction Severity Index (8). The Addiction Severity Index is a 45- to 60-minute structured interview, administered by a trained technician, that assesses degree of problem severity in seven areas in which substance abusers typically experience difficulties, including drug and alcohol use, criminal activity, employment, family/social functioning, and psychological health. The Addiction Severity Index is widely used in addictions treatment research and has been shown to be a reliable and valid instrument (9-11). In this study, baseline and follow-up data were gathered with the Addiction Severity Index.

National Institute of Mental Health Diagnostic Interview Schedule (DIS) (12). DSM-III-R axis I psychiatric diagnoses were obtained with this structured research interview.

Hopkins Symptom Checklist-90 (SCL-90) (13). This widely used and well-validated self-report instrument was used to assess patients' subjective level of emotional distress. The mean score was 70.52 (SD=60.02), with a range of 0-231.

Rating scale for resistance to treatment. During the first week of treatment, counselors rated patients on their degree of denial and resistance to treatment on an instrument with nine items taken from the Resistance to Treatment scale (which has six items) and the Resistance to Continuing Care scale (which has five items)

developed by Mee-Lee and Hoffmann (14). The internal consistency (α) of the scale was 0.93. The mean score was 13.0 (range=0–24); higher scores indicate greater acceptance of treatment.

Rating scale for social/family environmental status. During the first week of treatment, counselors rated the degree of support for sobriety and recovery in the patient's family/social network. The seven items were from the nine-item Social/Family Environmental Status scale, also developed by Mee-Lee and Hoffmann (14) for use with the Cleveland criteria. The α for this scale was 0.83. The mean score was 9.1 (range=1–21); higher scores indicate greater environmental support for sobriety.

Operationalizing the Cleveland Criteria

According to the Cleveland criteria, substance abusers should be referred to inpatient treatment if they reach a certain level of severity on any of the seven dimensions (6). The first two dimensions involve assessing the severity of the patient's withdrawal and/or physical complications. Because patients who have problems in these areas that are serious enough to warrant inpatient treatment were not referred to the intensive outpatient program, no attempt was made to evaluate these two dimensions.

The five dimensions of the Cleveland criteria on which patients were rated, the instruments used to rate patients on each of them, and the number of patients who qualified for inpatient treatment on each dimension according to the criteria were as follows.

Dimension 3: psychiatric complications. The Cleveland criteria propose that a patient requires inpatient care if he or she is currently depressed, suffering from a major personal loss, overly hostile, or displaying extreme emotions. Patients were rated as meeting the criteria for this dimension if they had current major depression (according to the DIS) or extreme symptom severity (SCL-90 score greater than 120) (N=36).

Dimension 4: life area impairments. The Cleveland criteria propose that patients who are violent when intoxicated or who have a legal or Employee Assistance Program mandate for comprehensive rehabilitation require inpatient care. Patients were rated as meeting the criteria for this dimension if they reported violent behavior in the preceding 30 days (Addiction Severity Index) (N=16).

Dimension 5: treatment acceptance/resistance. The Cleveland criteria propose that significant denial and minimization of the substance abuse problem preclude compliance with a lower level of care than inpatient treatment. Patients were rated as meeting the criteria for this dimension if they were rated by counselors as high on denial and treatment resistance (score of less than 10 on the scale for treatment acceptance/resistance) (N=30).

Dimension 6: loss of control/relapse crisis. The Cleveland criteria propose that patients who cannot remain substance free for at least 5 days or who require con-

tinuous use in order to function require inpatient care. Patients were rated as meeting the criteria for this dimension if they reported fewer than 5 days of abstinence (alcoholic patients) or fewer than 10 days of abstinence (cocaine-dependent patients) in the preceding 30 days or reported no abstinent periods of 30 days or more since beginning alcohol/drug use (all data from the Addiction Severity Index) (N=17).

Dimension 7: recovery environment. The Cleveland criteria propose that patients with seriously impaired social, family, or occupational functioning, or those with family members who are not supportive of treatment or who will undermine it in some way, require inpatient care. Patients were rated as meeting the criteria for this dimension if they were typically unemployed or had had no paid work days in the preceding 30 days (Addiction Severity Index), reported more than 9 days of family conflicts in the preceding 30 days or rated their family problems as severe (Addiction Severity Index), or were rated by their counselors as having a social environment not supportive of sobriety (rating of less than 7 on the scale for social/family environmental status) (N=69).

Treatment

After the baseline assessments, the subjects entered an intensive outpatient day treatment program that ran for 27 hours per week. The program generally lasted 4 weeks, although some patients dropped out and others stayed for up to 6 weeks. The program was focused on overcoming the patient's denial, helping the patient learn to cope with everyday problems and stresses, and teaching the patient about cues to relapse. Treatment consisted of 1) supervised milieu therapy, 2) group therapy with a cognitive-behavioral orientation, 3) education sessions three times per week covering information on the biopsychosocial aspects of addiction in a lecture/discussion format, 4) supervised group recreation weekly, and 5) family therapy with a social worker who had a master's degree. Individual counseling was also available as needed. Supervised urine drug screens were performed weekly, and patients were required to participate in at least three Alcoholics Anonymous or Narcotics Anonymous group meetings per week and to obtain a sponsor from the group.

Assessment of Outcome

Outcomes were assessed at 4 and 7 months with Addiction Severity Index composite scores, Addiction Severity Index self-reports of alcohol and cocaine use in the previous 30 days, and results of urine toxicology screens (cocaine patients only). The Addiction Severity Index composite scores are factor-like scores that assess severity of problems in seven separate areas (i.e., alcohol, drugs, medical, employment, legal, family/social, and psychological). The composite scores have a possible range of 0.00–1.00, with higher scores indicating greater problem severity; they have been shown to have

high reliability and good concurrent and predictive validity (9–11).

The standard Addiction Severity Index was administered only to subjects who could be interviewed within 6 weeks of their follow-up date, ranging from 2 weeks before follow-up to 4 weeks after the target date. Those who missed their targeted time frame but could be assessed at a later date were interviewed with an abbreviated form of the Addiction Severity Index ("retrospective" Addiction Severity Index) that yields days of substance use but not the composite scores. Prior to the analyses, the self-reports of alcohol and cocaine use were log transformed to normalize the distributions. However, the untransformed values are presented in the tables for ease of interpretation.

RESULTS

Of the 143 patients assessed at intake, 35 did not meet any of the Cleveland criteria for inpatient care, 55 met one of the criteria for inpatient care, 35 met two criteria, 14 met three, and four met four criteria. According to the criteria, therefore, 108 patients (58 alcoholic and 50 cocaine dependent) should have been assigned to inpatient rehabilitation rather than intensive day treatment. The outcomes of these patients were contrasted with the outcomes of the other 35 patients (12 alcoholic and 23 cocaine dependent) who were correctly matched to intensive day treatment according to the criteria.

Follow-up information from the Addiction Severity Index was available for 87% ($N=124$) of the patients at 4 months and 80% ($N=114$) at 7 months. Complete Addiction Severity Index data from the baseline and the two follow-up assessments were available for approximately 75% of the subjects (when any of the items making up a composite are left blank, the subject does not receive a composite score in that area). The follow-up rate was slightly higher among patients who were properly matched to intensive outpatient treatment (80%) than among those who met criteria for inpatient treatment (72%), although this difference was not statistically significant ($\chi^2=0.73$, $df=1$, $p>0.30$). Reports of number of days of alcohol or cocaine use from retrospective Addiction Severity Indexes were also available for four more patients at 4 months and 15 more at 7 months, which raised the follow-up rates to 89% at 4 months and 91% at 7 months. Follow-up urine toxicology data were available for 66% of the cocaine patients at 4 months and 58% at 7 months.

In terms of treatment participation, there were only slight differences between the groups. Those who qualified for inpatient care spent as many days in the program as those correctly matched to intensive day treatment (17.4 and 17.9 days, respectively; $t=-0.06$, $df=141$, $p>0.95$). A somewhat lower percentage of those who qualified for inpatient care completed the program (68.5% versus 74.3%), and they were also less likely to continue with aftercare (60.2% versus 65.7%), but

these differences were also not significant (for each measure, $\chi^2<0.42$, $df=1$, $p>0.50$).

Patients who qualified for inpatient care were contrasted with those who were correctly matched to intensive outpatient treatment on severity of psychosocial problems during follow-up, as represented by Addiction Severity Index medical, employment, legal, family/social, and psychological composite scores. The data were analyzed in repeated measures analyses of covariance (ANCOVA) with treatment criteria met (inpatient versus outpatient) as the grouping factor, baseline Addiction Severity Index composite score as the covariate, and Addiction Severity Index follow-up composite scores at 4 and 7 months as the repeated factor. Separate ANCOVAs were performed for each Addiction Severity Index composite score. Type of patient (cocaine dependent versus alcoholic) was also originally included as a grouping factor. However, none of the main effects or interactions that involved this factor approached significance, which indicated that the two types of patients could be combined.

The mean Addiction Severity Index composite scores for each group at baseline and at the two follow-ups are presented in table 2. After problem severity at baseline was controlled for, patients who qualified for inpatient treatment had significantly greater severity of psychological problems during follow-up. Although patients who qualified for inpatient treatment also had higher composite scores on the other four psychosocial problem severity composite measures of the Addiction Severity Index at 4 and 7 months, the differences between the groups were generally small, and none reached statistical significance. There were no significant main effects for the repeated factor with any of the Addiction Severity Index composite scores or significant Group by Time interactions, which indicates that the results in each group were stable over the two follow-up periods.

Data on alcohol and drug use and problem severity were also analyzed in repeated measures ANCOVAs. Separate analyses were done for the alcoholic and cocaine-dependent patients. For the alcoholic patients, the outcome measures were Addiction Severity Index alcohol composite score and number of days of alcohol use in the preceding 30 days at each follow-up point. The outcome measures for the cocaine patients were Addiction Severity Index drug composite score and number of days of cocaine use in the preceding 30 days. As in the previous analyses, the covariates were the baseline scores on each of the outcome measures, and the grouping factor was treatment criteria met (inpatient versus outpatient).

The results of these analyses are presented in table 3. Among both alcohol and cocaine patients, there were no significant differences between those meeting criteria for inpatient care and those correctly matched to intensive outpatient treatment on any of the measures of alcohol or drug use/problem severity during follow-up (all F values <0.60 , $p>0.45$). Once again, there were no significant main effects for the repeated factor or

^aAll patients received intensive outpatient treatment.^bHigher scores indicate greater problem severity. Unadjusted outcome scores are presented. All differences between groups, time effects, and the Group by Time interactions were nonsignificant.

significant Group by Time interactions, which indicates that the substance use results in each group were stable over the two follow-up periods. With the days-of-use measures, the analyses were repeated with data from the retrospective Addiction Severity Indexes included. With this larger sample, there were again no differences among the alcoholic or cocaine-dependent patients between those who met the criteria for inpatient treatment and those correctly matched to outpatient care.

The urine toxicology results are presented in table 4. At both the 4-month and 7-month follow-up points, there were no differences between cocaine-dependent

patients qualifying for inpatient treatment and those correctly matched to intensive outpatient care in the percentage with urine samples positive for cocaine or other drugs. At 4 months, about 32% of the patients had urine samples positive for cocaine, and about 12% had samples positive for other drugs. At 7 months, about 45% had samples positive for cocaine, while less than 5% had samples positive for other drugs. Although the overall follow-up rates for urine toxicology data were not particularly high, it should be noted that the percentage followed up was actually higher among patients qualifying for inpatient treatment, particularly

^aAll differences between groups were nonsignificant.

at 4 months. This suggests that the lack of difference between the groups was not due to a greater rate of missing urine toxicology data from patients meeting the criteria for inpatient care.

While the authors of the Cleveland criteria specify that patients need only qualify on one dimension to be referred to inpatient care, it is possible that somewhat more stringent guidelines would be more effective. We divided the patients on the basis of whether they met the criteria for inpatient care on *two or more* of the dimensions of the Cleveland criteria (N=53). We then compared the same group of patients who were correctly matched to intensive outpatient care (N=35) to this subgroup of 53 patients who were mismatched on the basis of ratings on two or more dimensions. The data were then analyzed with the repeated measures ANCOVA procedure we have described.

Again, there was little evidence that those who should have received inpatient care did any worse at the follow-ups. These patients did have significantly higher Addiction Severity Index composite scores on the family/social ($F=4.76$, $df=1$, 57 , $p<0.03$) and psychological ($F=9.12$, $df=1$, 53 , $p<0.01$) measures during follow-up. However, they did not have higher follow-up Addiction Severity Index medical, employment, or legal composite scores. Among the alcoholic patients, there were no differences in Addiction Severity Index alcohol composite scores or days of alcohol use between those qualifying for inpatient treatment and those properly matched to intensive outpatient care. Among the cocaine-dependent patients, there were no differences between the groups on Addiction Severity Index drug composite scores, days of cocaine use, or urine toxicology results. (The tables presenting the results of these analyses are available from the first author on request.)

Each of the five dimensions of the Cleveland criteria was also evaluated separately in an effort to determine whether one of these might be particularly predictive of poorer performance in day treatment. There was some evidence that patients who qualified for inpatient treatment on dimension 3 (psychiatric complications) or dimension 7 (recovery environment) were experiencing greater family and psychological difficulties during follow-up, as measured by Addiction Severity Index composite scores. Otherwise, there were no clear relation-

ships between any single Cleveland criterion and Addiction Severity Index outcome composite scores, reports of frequency of alcohol or cocaine use, or urine toxicology results during follow-up. (The tables presenting the results of these analyses are also available from the first author on request.)

DISCUSSION

Alcohol- and cocaine-abusing patients who were treated in an intensive outpatient program, but who qualified for inpatient treatment according to the Cleveland Admission, Discharge, and Transfer Criteria, were contrasted with other patients from the same program who were properly matched to intensive outpatient care according to the criteria. Surprisingly, there was little evidence that those who met the criteria for inpatient care were more likely to drop out of outpatient treatment and no evidence that they were drinking or using cocaine more frequently during either the 4- or 7-month follow-up. Furthermore, there was not much evidence to suggest that they were doing worse on any of the other outcome measures, with the exception of psychological status. Even this difference would not have been significant if a Bonferroni correction had been used to adjust the alpha level for the number of comparisons made.
